There is a lack of consensus for the diagnosis of pseudodementia. Carl Salzman and Janice Gutfreund (1986) argue that pseudodementia is neither pseudo nor dementia. They insist that it is a genuine impairment of memory secondary to depression without impairment of other mental processes. They believe it is helpful to differentiate patients both on the basis of mood and cognitive functions as well as on the basis of age. They use a four-category descriptive system, starting with the young-old (under the age of 80) who are mildly to moderately depressed. Then come the young-old who are severely depressed, followed by the old (older than 80 yrs.) who are mildly to moderately depressed: this is followed by the old who are severely depressed. These authors contend that the assessment of memory loss as a function of depression is relatively easy for the first group and increasingly difficult for the other three groups. In their opinion, the over-80 and severely depressed group may not be amenable to accurate assessment.

Muriel Lezak (1995) notes that the assumption underlying the diagnosis of pseudodementia is that the patient is neurologically sound. However, she points out that individuals with and without organic diseases have been given this diagnosis and that the pseudodementia diagnosis is often given when depressive symptoms are strongly noted and the diagnosis of primary dementia is not warranted.

The importance of distinguishing between depression and dementia in the elderly is vital. Very often, physicians will prescribe antidepressant medications if they suspect that a patient may be depressed. Although this may be helpful for younger patients, it may be less helpful for older patients, because antidepressant medications may be toxic for the elderly and, almost paradoxically, the chemical nature of some antidepressant drugs may actually produce memory impairment. Every effort should be made to differentiate dementia from pseudodementia, recognizing that neither dementia nor pseudodementia is a clearly defined category and that the assessment of pseudodementia is fraught with great difficulties, especially for those over 80 who are severely depressed.

PSI CHI

Psi Chi, the National Honor Society in Psychology, provides academic recognition to outstanding students interested in psychology. In its 73 years of existence it has also become an important source of opportunities for the intellectual, ethical, and social responsibility development of psychology students as it seeks to promote the highest ideals of the science and profession of psychology. Psi Chi is the oldest student organization in psychology still in existence and has the largest membership of any psychology-related organization in the world. Since its inception, Psi Chi has inducted over 420,000 members. It was the first organizational affiliate of the American Psychological Association (APA).

At both the local and national levels, Psi Chi seeks to enhance excellence in psychology. Membership is open to undergraduate and graduate students for whom psychology is a primary interest and who meet or exceed the minimum qualifications for membership (e.g., hours in psychology, grade point average, class rank). Individual membership is for life. Psi Chi is an affiliate of both the APA and the American Psychological Society and is also a member of the Association of College Honor Societies. It undertakes cooperative and mutually beneficial programming with Psi Beta, the National Honor Society for Community and Junior colleges.

Organization

The association has local chapters at over 1,000 U.S. higher education institutions, varying in size from small liberal arts colleges to large state universities. A council of elected members functions as a governing body, making decisions, setting policy, and facilitating the ongoing operation of the organization with the approval of the local chapters. National Council members consist of the president, past president, and president-elect; six vice-presidents representing geographical regions (Eastern, Midwestern, Rocky Mountain, Southeastern, Southwestern, and Western); and the executive officer. Day-to-day operations of administration, publication, promotion, record keeping, and so forth occur at the National Headquarters in Chattanooga, Tennessee, under the guidance of the executive officer.

Local chapters are organized and run by students with the help of faculty advisors. Officers are elected from the membership. Within the guidelines of the national organization, officers and members are responsible for recruiting and inducting new members, as well as planning and executing educational and social meetings and programs.

History

The idea for a national organization for students in psychology arose in a conversation between Frederick Lewis and Edwin Newman at the University of Kansas in 1927. A committee to study its feasibility was formed at a psychology meeting in May 1928, and additional work was undertaken at the APA convention in 1928. A constitution was written and approved at the first national meeting of the organization. This was held in conjunction with the Ninth International Congress of Psychology at Yale University, September 4, 1929. The organization began under another name but became officially known as Psi Chi in 1930. There were 22 charter chapters of the organization. In 1930 a newsletter was initiated, and the first *Psi Chi Handbook* appeared in 1932.

Issues confronted early on by Psi Chi included appropriate activities for the organization, who should be admitted to membership—with one exception the early chapters were all from larger colleges and universities—and the question of honorary members. During World War II national meetings were not held, but the postwar years saw considerable growth in the number of chapters and members. In addition to change associated with growth, the 1950s saw the first Psi Chi student research award (1950), the formal affiliation of Psi Chi with APA (1958), and the initiation of Psi Chi–sponsored speakers at the annual APA meeting (1959). This program has featured many distinguished scholars including, for example, E. G. Boring, Otto Klineberg, Jerome Bruner, Rollo May, Neal Miller, Carl Rogers, and B. F. Skinner. More recently, changes in the organization have involved the addition of several awards and grants, changes in the structure of the National Council, and the designation and affirmation of Psi Chi as an honor society rather than a professional society. Over the years Psi Chi has enjoyed and benefited from strong leadership from the National Council, the National Office, and local chapters. Undoubtedly the most notable leadership contributions were those of Ruth H. Cousins, who from 1958 to 1991—during most of which she served as executive director—provided tireless and inspired leadership that shaped the identity and efficiency of the modern Psi Chi organization.

Functioning

Local chapters engage in a wide variety of activities addressing the academic, social, and service needs of the membership. Invited speakers; student recognition of excellence in teaching; sessions on applying to graduate school; research fairs; student-faculty social gatherings; volunteering at mental health, childcare, medical, and charitable facilities; group research projects; university and collegiate service activities; field trips; and tutoring services are just a few examples of the many varied activities undertaken by local chapters. Individually, these activities afford opportunities for incidental and direct learning, professional exploration, recognition of accomplishments, good-natured fellowship, and the exercise of leadership. Collectively, these activities augment and enrich the curricular experiences of students in psychology.

The national organization sponsors student paper and poster sessions at regional and national meetings and provides certificate recognition of outstanding student scholarship, as well as supporting student research more generally. For example, it now provides monetary support for undergraduate research conferences. It provides research awards for undergraduate and graduate students, research grants for students and faculty, and recognition awards for outstanding chapters and faculty advisors. Currently, Psi Chi provides $180,000 annually through its grants and awards programs. Psi Chi publishes *Eye on Psi Chi,* a quarterly magazine featuring articles of interest to psychology students and faculty. Issues such as preparing for graduate school, career planning, and increasing the vitality of Psi Chi chapters, as well as information regarding meetings and Psi Chi awards and grant programs are routinely presented. Finally, the organization publishes the *Psi Chi Journal of Undergraduate Research,* which presents original empirical research primarily designed, conducted, and written by undergraduate members.

PSYCHOANALYTIC STAGES

Psychoanalytic stages, or psychosexual stages, are stages of psychosexual development postulated by Sigmund Freud to account for personality development. Based on the assumption that early childhood experiences significantly influence adult personality, social experiences at each stage presumably leave some permanent residue in the form of attitudes, traits, and values acquired at that stage. Further, it is assumed that a certain amount of sexual energy (libido) is present at birth and thereafter progresses through these psychosexual stages. More specifically, Freud theorized that the central theme running through personality development is the progression of the sex instinct through four universal stages—oral, anal, phallic, and genital. A period of *latency* intervenes between the latter two psychosexual stages but, strictly speaking, it is not a stage. Freud assigned crucial significance to the first three stages, termed *pregenital* stages, in the formation of adult character structure.

The Oral Stage

During the oral stage of psychosexual development, which lasts approximately throughout the first year of life, the primary erogenous zone is the mouth. Through activities associated with the mouth—sucking, swallowing, biting—infants experience their first continuous source of pleasure, and thus the mouth region becomes a focal point of rudimentary psychosexual satisfaction. Fixation in the oral-aggressive phase (enter teeth), earmarked by biting and chewing activities, may result in a bitingly sarcastic, argumentative, and hostile adult personality. From the psychoanalytic perspective, then, there is little wonder why people experience serious difficulties in giving up such verbal behaviors—ultimately their psychological roots can be traced back to the first year of life.

The Anal Stage

During the second and third years of life, the primary erogenous zone is the anus. Children at this stage are thought to derive considerable pleasure from temporary retention of feces (i.e., permitting minor pressure to be exerted against the lower intestine and anal sphincter) or expulsion of feces (i.e., immediate tension reduction). With the onset of parentally controlled toilet training, however, the child's pleasures in this regard encounter the stiff opposition of social restraints, and various fixations may thus occur. Reflecting the assumption of the importance of early childhood experience in personality formation, Freudians believe that their approach to toilet training forges the way for the development of adult productivity and creativity.

The Phallic Stage

The genitals become the primary erogenous zone during the phallic stage of psychosexual development, which extends from the fourth through the fifth years of life. During this stage, children can be observed examining their sex organs, masturbating, and showing interest in matters pertaining to birth and sex. But perhaps more important, this period of life serves as the stage on which the most critical psychological drama of childhood is played out—the Oedipus complex. Freud theorized that every child unconsciously wishes to possess the opposite-sexed parent and simultaneously dispose of the same-sexed parent.

Freud believed that the boy experiences intense conflict over his incestuous desires toward the mother and fears retaliation from the father for such desires. Specifically, the small boy fears that the father will discover his sexual desires and retaliate by cutting off the boy's penis.

The little girl during the phallic stage is depicted as discovering that, unlike her father, she lacks a penis. Immediately following this anatomical discovery, the girl wishes she had one—a desire which, in psychoanalytic theory, is called *penis envy.* Penis envy in girls is roughly equivalent psychologically to castration anxiety in boys, and together, penis envy and castration anxiety are known as the castration complex in Freudian theory.

Failure to resolve the Oedipus conflict and unresolved Oedipal feelings lie at the root of many psychological disorders, when viewed from the perspective of psychoanalytic theory.

The Genital Stage

As the Oedipus complex becomes resolved, the child is presumed to move into a period of latency (lasting approximately from age 6 to 12) in which the sex instinct remains relatively dormant and psychic energy is redirected into nonsexual activities, such as school and athletics. With the onset of puberty, however, genital sexuality is reawakened and the genital stage of psychosexual development, extending from puberty until death, begins. During the genital stage, narcissistic strivings become fused with, and largely transformed into, the seeking of heterosexual relationships involving mutual gratification. Thus the adult genital personality type, the successful end product of psychosexual development in psychoanalytic theory, is characterized by a capacity for mature heterosexual love, responsible concerns beyond the self, and productive living in society.

PSYCHOENDOCRINOLOGY

Hormones are substances, such as steroids and peptides, synthesized and released from endocrine glands, cell clusters, or specialized cells and spread over the brain, lungs, or gastrointestinal tract. Several of these hormones exist both in the brain and peripheral organs, where they act as an endocrine or paracrine messenger, or even as a neurotransmitter. Most endocrine activities vary with sex and age, and many show pronounced variations over the course of the month or even the day.

Psychological events profoundly modulate the release of hormones either directly, via the brain, or indirectly, via the autonomic nervous system. These hormones, in turn, influence psychological events either directly or indirectly. Psychoendocrinology is interested in investigating the interface between the endocrine systems and mood, cognition, and behavior. Most of this research is presently done in animal experiments. However, the ability to assess steroids in saliva has considerably facilitated research with human subjects. Furthermore, new and highly sensitive immunoassays, advances in neuroendocrine techniques, and the development of specific pharmacological tools have rapidly increased our knowledge in psychoendocrinology.

The hypothalamic-pituitary-adrenal axis (HPAA) has been of particular interest as the major pathway through which the brain responds to psychological stress. Corticotropin-releasing factor (CRF) from cells of the paraventricular hypothalamus acts as a releasing hormone for adrenocorticotropin (ACTH) in the pituitary, and ACTH releases corticosteroids from the adrenal cortex. Corticosteroids (cortisol, corticosterone) are essential for the body and allow psychological and physical adaptation to stressors. In addition, they exert a negative feedback on the release of CRF and ACTH. Disturbances of the HPAA are associated with both mental and physical illness. CRF can easily be activated by stress and promotes depression, anxiety, and other forms of behavioral pathology. By activating the autonomic nervous system, CRF further links psychological stress to gastrointestinal and cardiovascular disorders. Although homeostasis of the HPAA is maintained by negative feedback, permanently enhanced and lowered glucocorticoid levels have been observed under prolonged stress. While hypercortisolemia is associated with depression, cognitive dysfunction, inflammatory diseases, and the metabolic syndrome, hypocortisolemia has been found in patients with fibromyalgia, chronic pelvic pain, irritable bowel disease, chronic fatigue syndrome, and Posttraumatic Stress Disorder. The molecular mechanisms by which CRF and glucocorticoids facilitate these disorders are presently under investigation. New techniques allow researchers to assess receptor function and receptor polymorphisms, and to identify regions in the human body where hormones exert their behavioral effects.

The hypothalamic-pituitary-gonadal axis (HPGA) and the hypothalamic-pituitary-thyroid axis (HPTA) are other important endocrine pathways linking psychological events to organic function. Both systems are comparably controlled by negative feedback. Sexual cues can stimulate the HPGA, while stress inhibits the HPGA via CRF, thus promoting stress-induced infertility. Sex steroids such as testosterone, progesterone, and estradiol profoundly affect brain function, behavior, cognition, and mood. Such effects

can become clinically relevant, as in the premenstrual syndrome or postpartum depression. Hyperthyroidism, which is usually caused by organic diseases, leads to psychological alterations such as irritability, hyperactivity, and heat intolerance. Hypothyroidism, on the other hand, provokes lethargy, depression, fatigue, and cold intolerance. Other hormones from the anterior pituitary, such as prolactin and growth hormone (GH), are also released by stress. However, there is not yet a clear picture of the role of these hormones in stress-related disorders.

Vasopressin and oxytocin are peptide hormones, mainly released by the posterior pituitary. Vasopressin has vasoconstrive and antidiuretic properties, and has been considered relevant for stress effects on blood pressure and enuresis nocturna. Recent evidence suggests that it is beneficial for psychoendocrinology not to separate the role of a given substance from its function as an endocrine messenger or a neurotransmitter. Oxytocin promotes labor in pregnant women when the baby's head distends the uterus wall, and the release of milk is initiated by the suckling newborn. Oxytocin is closely associated with social attachment and bonding, and a social partner again initiates both psychological events. Therefore, it seems that another significant individual within a reproductive context activates this substance, both as a neurotransmitter and as a hormone. While oxytocin receptor functions are facilitated by estrogens, testosterone modulates vasopressin receptors. For example, it has been shown that the flank-marking behavior of hamsters is regulated by vasopressin, but strongly dependent upon testosterone.

Recent evidence has shown that endocrine systems are strongly influenced by pre- and postnatal events. Stress or infections of the mother, raising glucocorticoid levels, or reduced maternal care after birth seem to result in a lifelong programming of specific hormone receptors. There is already strong evidence that these determinants account for later vulnerability for hypertension, diabetes II, and visceral obesity. Even later in life, chronic and traumatic stress can induce permanent endocrine changes and enhance vulnerability for specific diseases.

The endocrine system closely and bidirectionally interacts with both the autonomic nervous system and the immune system. Thus, psychoendocrinology has to consider the full interplay of biological events, which affect cognitive, affective, and behavioral events and disturbances. The rapid acquisition of data and information has already been successfully transferred into clinical applications: several endocrine challenge tests have already been developed to aid in the diagnosis of mental and stress-related disorders. Additionally, new therapeutic treatments can be developed: After the discovery of the important role of CRF and CRF-receptors in depression, for example, a new group of antidepressants is presently being developed that block the respective CRF-receptors. Furthermore, new tools—such as the intranasal application of neuroactive hormones like melanocortin, insulin, vasopressin, oxytocin, or leptin—provide new routes for psychoactive drugs.

New hormones are continously being discovered, and it is clear that these discoveries will continue to stimulate psychoneuroendocrinology research. The peptides PYY 3-36 or ghrelin, for example, are gut-derived hormones, both of which regulate food intake via effects on the central nervous system. Obviously, both hormones will contribute considerably to our understanding of food intake and eating disorders, thus illustrating the complexity and potential benefits of research in psychoendocrinology.

PSYCHOLOGICAL ASSESSMENT

Psychological assessment is considered one of the most important functions in applied psychology. In psychological assessment the practitioner uses observation, interviews, and psychological tests to gain information about the client's personality characteristics, symptoms, and problems in order to arrive at practical decisions about their behavior. In an assessment study the practitioner identifies the main sources of a client's problems and attempts to predict the likely course of events under various conditions.

Mental health patients may present with behavioral, emotional, or physical discomforts that are often difficult for a clinical practitioner to understand initially. Usually, in mental health settings a clinical psychologist attempts to understand the nature and extent of the patient's problem through a process of inquiry that is similar to the way a detective might approach a case: by collecting evidence and using inductive and deductive logic to focus on the most likely factors. Assessment of mental disorders is usually more difficult, more uncertain, and more protracted than it is for evaluation of many physical diseases. Yet early assessment of mental health problems is extremely important in clinical practice—no rational, specific treatment plan can be instituted without at least some general notion of what problems need to be addressed.

In order for psychological assessment to proceed effectively, the person being evaluated must feel a sense of rapport with the clinician. The assessor needs to structure the testing situation so that the person feels comfortable. Clients need to feel that the testing will help the practitioner gain a clear understanding of their problems, to understand how the tests will be used, and to understand how the psychologist will incorporate test results in the clinical evaluation.

What does a clinician need to know in a psychological

assessment? First, of course, the problems must be identified. Are they of a situational nature; that is, have they been precipitated by some environmental stressor, or are the problems more pervasive and long-term? Or is it perhaps some combination of the two? Is there any evidence of recent deterioration in cognitive functioning? How long has the person had the symptoms and how is he or she dealing with the problem? What, if any, prior help has been sought? Are there indications of self-defeating behavior or low self-esteem, or is the individual using available personal and environmental resources? Following are several important areas to be considered in a psychological assessment.

Personal History

It is important to have a basic understanding of the individual's history and development, family history (whether the person has relatives with a history of mental illness), intellectual functioning, personality characteristics, and environmental pressures and resources. For example, how does the person characteristically respond to other people? Are there excesses in behavior present, such as eating or drinking too much? Are there notable deficits, for example in social skills? Does the person show any inappropriate behavior?

Personality Factors

Assessment needs to include a description of any relevant long-term personality characteristics. Has the person behaved in deviant or bizarre ways in particular situations; for example, in circumstances requiring submission to legitimate authority? Do there seem to be personality traits or behavior patterns that predispose the individual to behave in maladaptive ways across a broad range of situations? Does the person tend to become dependent on others to the point of losing his or her identity? Is the person able to accept help from others? Is the person capable of accepting appropriate responsibility for others' welfare? Such questions are necessarily at the heart of many assessment efforts.

Social Situations

It is also important to evaluate the social contexts in which the individual functions. What environmental demands does the person face? What emotional support or special stressors exist in the person's life?

The diverse information about the individual's personality traits, behavior patterns, and environmental demands must be integrated into a consistent and meaningful picture often referred to as a *dynamic formulation* because it describes the current situation and provides hypotheses about what is driving the person to behave in maladaptive ways. The clinician should try to arrive at a plausible explanation; for example, a reason why a normally passive and mild-mannered man suddenly flew into a rage and became physically abusive toward his wife. The formulation will allow the clinician to develop hypotheses that might explain the client's future behavior. What is the likelihood that the person would get worse if the problems are left untreated? Which behaviors should be the initial focus of change, and what treatment methods are likely to be most efficient in producing this change? What changes might reasonably be expected if the person were provided a particular type of therapy?

Clients who are being assessed in a clinical situation are usually highly motivated to be evaluated and usually like to know the results of the testing. They usually are eager to give some definition to their discomfort. In many situations it is important to incorporate information from a medical evaluation into the psychological assessment in order to rule out physiological abnormalities that may be causing or contributing to the problem.

Clinical assessment attempts to provide a comprehensive picture of an individual's psychological functioning and the stressors and resources in his or her life situation. In the early stages of the process, the assessment psychologist attempts to obtain as much information about the client as possible—including present feelings, attitudes, memories, demographic facts, and important formative life events—and trying to fit the diverse pieces together into a meaningful pattern. Starting with a global technique, such as a clinical interview, clinicians may later select more specific assessment tasks or tests. The following procedures are some of the methods that may be used to obtain the necessary data.

The Assessment Interview

The assessment interview is usually the initial and often the central information source in the assessment process. This is usually a face-to-face interaction in which information about various aspects of a patient's situation, behavior, past history characteristics, and personality is acquired. The initial interview may be relatively open in format, with an interviewer deciding about his or her next question based on the client's answers to other ones, or it may be more structured so that a planned set of questions is followed. In structured interviewing the clinician may choose from a number of possible interview formats whose reliability has been established in research. The structured interviewing approach is likely to be more reliable but may be less spontaneous than the free-response interview.

Clinical interviews can be subject to error because they rely upon human judgment to choose the questions and process the information. The assessment interview can be made more reliable by the use of rating scales that serve to focus inquiry and quantify the interview data. For example, the person may be rated on a three-, five-, or seven-point

scale with respect to suicide potential, violence potential, or other personality characteristics, depending upon the goals of the assessment.

The Clinical Observation

One of the most useful assessment techniques that a clinician has for gaining patient-relevant information is direct observation. Observation can enable the clinician to learn more about the person's psychological functioning; for example, personal hygiene, emotional responses, and such pertinent characteristics as depression, anxiety, aggression, hallucinations, or delusions. Clinical observation is probably more effective if conducted in the natural environment (such as a classroom or home); however, it is more likely to take place upon admission to or in the clinic or hospital ward.

Clinical observation can provide more valuable information in the clinical situation if it is objectively structured; for example, the use of structured rating scales helps maintain objectivity. The most useful rating scales are those that enable a rater to indicate not only the presence or absence of a particular behavior but also its prominence. Standard rating scales can provide a quantifiable format for rating clinical symptoms. For example, the Hamilton Anxiety Rating Scale (Hamilton, 1959) specifically addresses behavior related to the experience of intense anxiety and has become almost the standard for assessing anxiety states. Observations made in clinical settings by trained observers can provide behavioral data useful in ongoing clinical management of patients, for example, to focus on specific patient behaviors to be changed.

Psychological Tests

Psychological tests are standardized sets of procedures or tasks for obtaining samples of behavior. A client's responses to the standardized stimuli are compared with those of other people having comparable demographic characteristics, usually through established test norms or test score distributions. Psychological tests are useful diagnostic tools for clinical psychologists in much the same way that blood tests or X-ray films are useful to physicians in diagnosing physical problems. In all these procedures, problems may be revealed in people that would otherwise not be observed. The data from tests allow a clinician to draw inferences about how much the person's psychological qualities differ from those of a reference norm group, typically a sample of "normal" persons. Psychological tests have been developed to measure many psychological attributes in which people vary. Tests have been devised to measure such characteristics as coping patterns, motive patterns, personality factors, role behaviors, values, levels of depression or anxiety, and intellectual functioning.

Two types of psychological tests are typically incorporated in psychological assessments in clinical practice—intelligence tests and personality tests.

Intelligence Tests

In many cases it is important to have an evaluation of the person's level of intellectual functioning. The clinician can assess intellectual ability with a wide range of intelligence tests. For example, if the patient is a child, the Wechsler Intelligence Scale for Children-Revised (WISC-III) or the current edition of the Stanford-Binet Intelligence Scale might be used for measuring the child's intellectual ability. For measuring adult intelligence, the Wechsler Adult Intelligence Scale-Revised (WAIS-III) is the most frequently used measure.

Individually administered intelligence tests—such as the WISC-R, WAIS-III, and the Stanford-Binet—are labor-intensive and typically require 2 to 3 hours to administer, score, and interpret. The information obtained about the cognitive functioning of patients, however, can provide useful hypotheses about the person's intellectual resources and ability to deal with problems.

Personality Tests

The clinician would likely employ several tests designed to measure personal characteristics. Personality tests are of two general types—projective and objective tests.

Projective Techniques

Projective techniques are unstructured tasks; for example, the clinician might use ambiguous stimuli, such as incomplete sentences which the person is asked to complete. The individual's responses to these ambiguous materials are thought to reveal a great deal about their personal problems, conflicts, motives, coping techniques, and personality traits. One important assumption underlying the use of projective techniques is that the individual (in trying to make sense out of vague, unstructured stimuli) tends to "project" their own problems, motives, and wishes into the situation, because they have little else on which to rely in formulating their responses to these materials. Projective tests are considered to be valuable in providing clues to an individual's past learning and personality. The three most frequently used projective tests are the Sentence Completion Test, the Thematic Apperception Test (TAT), and the Rorschach. Due to space considerations this article will examine only the Rorschach and the TAT.

The Rorschach test was developed by the Swiss psychiatrist Rorschach in 1911. Using 10 inkblot pictures, the person is instructed to look at each card and tell "what it looks like or reminds you of." After the initial responses to all the cards are recorded, the examiner then goes back through

the responses to determine "what about the inkblot made it look the way it did." Once the responses are obtained, the clinician must then interpret them—this normally involves scoring the protocol according to a standard method in order to determine what the responses mean. The most widely used and reliable scoring system is the Exner Comprehensive System (Exner, 1993). The indexes resulting from the scoring summary are then employed to explore the literature to determine the meaning of the responses. Experience with the instrument is extremely important in arriving at useful hypotheses about clients.

The Thematic Apperception Test (TAT) was introduced in 1935 by Morgan and Murray as a means of studying personality traits. The TAT uses a series of pictures about which a subject is instructed to create stories. The content of the pictures is highly ambiguous as to actions and motives, so that people tend to project or attribute their own conflicts and worries into their stories. Interpretation of the stories is impressionistic. The interpreter reads the constructions and determines what potential motives and behavioral tendencies the respondent might have that led them to "see" the pictures in the ways they did. The content of the TAT stories is thought to reflect the person's underlying traits, motives, and preoccupations.

Projective tests, like the Rorschach and TAT, can be valuable in many clinical assessment situations, particularly in cases where the task involves obtaining a comprehensive picture of a person's personality makeup. The great strengths of projective techniques are their unstructured nature and their focus on the unique aspects of personality. However, this is also a weakness, because their interpretations are subjective, unreliable, and difficult to validate. In addition, projective tests typically require a great deal of time to administer and advanced skill to interpret. The clinician must also employ more objective tasks in order to put the client's symptoms and behavior in an appropriate perspective.

Objective Personality Scales—The MMPI-2 Objective tests are *structured* in that they use questions or items that are carefully phrased. In giving alternative responses as choices, they provide a more controlled format than projective instruments and thus are more amenable to quantifiable response analysis, which in turn enhances the reliability of test outcomes. The most widely used of the major structured inventories for personality assessment is the Minnesota Multiphasic Personality Inventory (MMPI), now known as the MMPI-2 after a revision in 1989 (Butcher, Dahlstrom, Graham, Tellegen, & Kaemmer, 1989). It is described here because it is the most widely studied test in this class of instruments, and because in many ways it is the most successful of the class.

The MMPI was introduced for general use in 1943 by Hathaway and McKinley. Today, it is the most widely used personality test for both clinical assessment and psychopathologic research in the United States and is the assessment instrument most frequently taught in graduate clinical psychology programs. Moreover, translated versions of the MMPI-2 are widely used internationally (Butcher, 1996). The MMPI-2 consists of 567 items covering topics ranging from physical symptoms to psychological problems to social attitudes. Normally, subjects are encouraged to answer all of the items either *true* or *false*.

The MMPI-2 is interpreted using scoring scales that have been devised to measure clinical problems. The MMPI clinical scales were originally developed by an empirical item-selection method. The pool of items for the inventory was administered to a large group of normal individuals and several quite homogeneous groups of clinical patients who had been carefully diagnosed. Answers to the items were then analyzed to see which ones differentiated the various groups. On the basis of these findings, the clinical scales were constructed, each consisting of the items that were answered by one of the patient groups in the direction opposite to the predominant response of the normal group. This method of item selection, known as empirical keying, produced scales that were valid in predicting symptoms and behavior. If a person's pattern of true/false responses closely approximate that of a particular group, such as depressed patients, it is a reasonable inference that he or she shares other psychiatrically significant characteristics with the group—and may in fact be functioning "psychologically" like others in that group.

Each of these clinical scales measures tendencies to respond in psychologically deviant ways. Raw scores of a client are compared with the scores of the normal population, many of whom did (and do) answer a few items in the critical direction, and the results are plotted on the standard MMPI-2 profile form. By drawing a line connecting the scores for the different scales, a clinician can construct a profile that shows how far from normal a patient's performance is on each of the scales. The Schizophrenia scale, for example, is made up of the items that schizophrenic patients consistently answered in a way that differentiated them from normal individuals. People who score high (relative to norms) on this scale, though not necessarily schizophrenic, often show characteristics typical of the schizophrenic population. For instance, high scorers on this scale may be socially withdrawn, have peculiar thought processes, may have diminished contact with reality, and in severe cases may have delusions and hallucinations.

One extremely useful feature of the MMPI-2 is that it contains a number of scales to evaluate test-taking attitudes. It includes a number of validity scales to detect whether a patient has answered the questions in a straightforward, honest manner. For example, there is one scale that detects lying or claiming extreme virtue and several scales to detect faking or malingering. Extreme endorsement of the items on any of these measures may invalidate the test.

The MMPI-2 is used in several ways to evaluate a pa-

tient's personality characteristics and clinical problems. The traditional use of the MMPI-2 is as a diagnostic standard. The individual's profile pattern is compared with profiles of known patient groups. If the client's profile matches that of a particular group, information about patients in this group can suggest a broad descriptive diagnosis for the patient under study. A second approach to MMPI interpretation is referred to as content interpretation. This approach is used to supplement the empirical interpretation by focusing on the content themes in a person's response to the inventory. For example, if an individual endorses an unusually large number of items about depression, a clinician might well conclude that the subject is preoccupied with low mood.

Applications of Clinical Assessment

Assessment in Mental Health Settings

Most clinical assessment is undertaken in medical, psychiatric, or prison settings to evaluate the mental health status of people with problems. The practitioner would administer, score, and interpret the battery of tests, usually at the beginning of the clinical contact, and develop an integrated report. The report would likely focus on such tasks as developing mental health treatment plans (Beutler & Berran, 1995).

Psychological Assessment in Forensic or Legal Cases

One of the fastest-growing applications of psychological tests involves their use in evaluating clients in court cases. Psychological tests have been found to provide valuable information for forensic evaluations—particularly if they contain a means of assessing the person's test-taking attitudes (such as the MMPI-2, which contains several measures that provide an appraisal of the person's cooperativeness or frankness in responding to the test items). Many litigants or defendants in criminal cases attempt to present themselves in a particular way (for example, to appear disturbed in the case of an insanity plea or impeccably virtuous when trying to present a false or exaggerated physical injury). These motivations to "fake good" or "fake bad" tend to result in noncredible test patterns.

Because of their scientific acceptability, well-known psychological tests, such as the WAIS-III and MMPI-2, are widely accepted by courts as appropriate assessment instruments. In order for a test to be allowed into testimony, it must be shown to meet an accepted scientific standard. The primary means of assuring that tests are appropriate for court testimony is that they are standardized and are not experimental procedures (Ogloff, 1995). Psychological assessments in court cases can provide information about the mental state of felons on trial, assess the psychological adjustment of litigants in civil court cases, and aid in the determination of child custody in divorce cases.

Psychological Tests in Personnel Screening

The use of personality tests in employment screening has a long tradition; the first formal use of a standardized personality scale in the United States was implemented to screen out World War I draftees who were psychologically unfit for military service (Woodworth, 1920). Today, personality tests are widely used for personnel screening in occupations that require great public trust. Some occupations, such as police officers, airline flight crews, fire fighters, nuclear power plant workers, and certain military specialties require greater emotional stability than most other jobs. Maladaptive personality traits or behavior problems in such employees can result in public safety concerns. For example, someone who behaves in an irresponsible manner in a nuclear power plant control room could significantly endanger the operation of the facility and the safety of the surrounding community. The potential for problems can be so great in some high-stress occupations (e.g., air traffic controllers) that measures need to be taken in the hiring process to evaluate applicants for emotional adjustment.

Personnel screening for emotional stability and potentially irresponsible behavior requires a somewhat different set of assumptions than clinical assessment. One assumption is that personality or emotional problems, such as poor reality contact, impulsivity, or pathological indecisiveness, would adversely affect the way in which a person would function in a critical job. Psychological tests should not be the sole means of determining whether a person is hired. Psychological tests are more appropriately used in the context of an employment interview, a background check, and a careful evaluation of previous work records.

Summary

Psychological assessment is one of the most important and complex activities undertaken by clinical psychologists. The goals of psychological assessment include describing the individual's symptoms, identifying possible causes, evaluating the severity of the problem, and exploring the individual's personal resources, which might be valuable in the decisions to be made.

A broad range of psychological assessment methods is used for gathering relevant psychological information for clinical decisions about people. The most flexible assessment methods are the clinical interview and behavioral observation. These methods can provide a wealth of clinical information. Psychological tests are used to measure personality characteristics by employing standardized stimuli for collecting behavior samples that can be compared with those of other individuals through test norms. Two different personality testing methods have been employed: projective tests, such as the Rorschach, in which unstructured stimuli are presented to a subject who then "projects" meaning or structure onto the stimulus, thereby revealing

"hidden" motives, feelings, and so on; and objective tests, or personality inventories, in which a subject is required to read and respond to itemized statements or questions. Objective personality tests usually provide a cost-effective way of collecting personality information. The MMPI-2 provides a number of clinically relevant scales for describing abnormal behavior. Psychological tests are widely used for making clinical decisions in mental health settings, forensic applications, and personnel screening for positions that require emotionally stable employees.

PSYCHOLOGICAL HEALTH

All psychotherapeutic systems have a view of human nature, a concept of disease etiology, and a vision of psychological health. The intention of therapy is to work toward the vision of psychological health as defined by each particular orientation. The vision of psychological health as defined by each approach is predicated upon and consistent with its view of human nature. These views can be understood as paradigms, or "world hypotheses" that professionals operate from in pursuing their work. While such paradigms are necessary to make sense out of our lives and work, they can also be limiting. For example, psychology has traditionally been pathology based, viewing psychological health as the mere absence of symptoms, as evidenced by the *Diagnostic and Statistical Manual of Mental Disorders.*

Reflecting a dissatisfaction with pathology-based clinical and mental health classifications, some researchers are developing and empirically investigating models of positive health, including non-Western models. These investigations suggest that elimination of pathology may give us the concept of the "average" or "normal" rather than a concept of true positive or "optimal" psychological health.

Five Views of Human Nature and Psychological Health

This section presents five views of human nature and their respective views of psychological health—the goal of therapy (Table 1).

Biomedical Approach

View of Human Nature. The biomedical paradigm, which guides modern medicine and psychiatry, views human nature as determined in large part by our biological/physiological processes. An example is the biomedical approach to depression. Assessment leads to a precise diagnosis for which an organic cause is identified (e.g., lack of serotonin), then a treatment specific to the pathology is prescribed (e.g., SSRI—serotonin specific reuptake inhibitor).

Goal of Therapy. The goal of therapy is to alleviate undesired symptoms via medication, restore biochemical homeostatis, and thereby achieve "psychological health."

Psychodynamic Approach

View of Human Nature. Psychodynamic psychology views behavior as a product of competing instincts, needs, and impulses. Although there are many schools, all subscribe to the same basic premise, namely that man is, in Freud's terms, "lived by unknown and controlled forces" which originate in the amoral id. Since these mental forces are unconscious, a person is not fully aware of how they are manifested, and the result of this conflict is neurosis, or "mental illness."

Goal of Therapy. From a psychodynamic view of human nature, psychological health is achieved by uncovering the repressed facts of the self—"to make the unconscious conscious"—and bringing these repressed desires, fears, and depressions into consciousness: "Where id was, ego shall be."

Behavioral/Cognitive Approach

View of Human Nature. The cognitive-behavioral approach views human nature as a *tabula rasa,* a blank slate. The individual is motivated by environmental stimuli and social interactions (or cognitive representations of the two). Therefore, psychological maladjustment is likely to result

Table 1. Comparison and Contrast of Five Schools of Psychotherapy

Subject	Biomedical	Psychodynamic	Cognitive-Behavioral	Humanistic-Existential	Transpersonal
View of human nature	Primarily biological/ physiological processes.	Ruled by unconscious, amoral id.	Blank slate. Determined by environmental stimuli, or cognitive representations of stimuli.	Innately self-actualizing (H). Existence precedes essence (E).	Interconnected. Capable of going beyond ego identity.
Goal of Psychotherapy	Normalize chemical imbalances.	To make the unconscious conscious, "where id was, ego shall be."	Competently respond to environment. Reinterpret illogical cognitions.	Foster self-actualization (H). "Choices" create authentic self (E).	Go beyond identification with limited ego. See interconnection with others and world.

from maladaptive learning, reinforcement patterns, and/or cognitive distortions.

Goal of Therapy. A cognitive-behavioral approach teaches clients to identify and reinterpret the illogical notions that underline their distressing symptoms. Psychological health is achieved when maladaptive patterns (cognitive and behavioral) are recognized and changed, consequently alleviating undesired symptoms.

Humanistic/Existential Approach

View of Human Nature. The humanistic/existential approach views the individual as neither controlled by a "genetic" amoral id nor by external stimuli. The humanistic approach instead views the individual as constantly changing or "becoming," with an innate self-actualizing nature. The existential approach argues there is no innate self-actualizing nature—existence precedes essence—and therefore a person must "create his/her authentic self." The unhealthy person, from a humanistic/existential perspective, is one who restricts the task of openly discovering and making sense of his or her existence, turns away from the responsibility of creating choices, and fails to relate to others and the world authentically in the present moment.

Goal of Therapy. The goal of humanistic/existential therapy is to foster self-actualization, allowing the client to assume full responsibility for developing his/her identity. Ultimately, this entails authentically encountering the human environment, facing the inevitability of isolation and mortality, and realizing that if I cannot choose my fate, I can nevertheless choose my attitude toward it.

Transpersonal Approach

View of Human Nature. The transpersonal approach views human nature as having an interconnected "essence" and an innate motivation toward values that transcend the self.

Goal of Therapy. Within the transpersonal tradition, the goal of therapy is to extend the identity or sense of self beyond the "narrow self" so that individuals realize their interconnection with others and the world. The qualities of the healthy person include realizing the limits of ego identity, developing compassion, opening oneself up to peak experiences, being aware of unitive consciousness, and embracing ultimate values.

Toward a More Systemic Approach to Psychological Health

Each of the above traditions has a view of human nature and an understanding of psychological health based on its own paradigmatic view. A more complete view of psychological health may need to integrate the unique perspective offered by each tradition in order to maximize health on the physical, mental, social, and spiritual levels.

Such a multilevel systemic view of psychological health is complementary, rather than exclusive, addressing issues and pathologies at various developmental levels. For example, a comprehensive treatment plan for depression, depending upon the client, may include addressing biochemical imbalances (biomedical), learning coping strategies to handle environmental stressors and behavioral repertoire deficits (behavioral), interpreting cognitive distortions (cognitive), overcoming lack of trust in oneself (humanistic), examining unconscious psychodynamic and intrapsychic conflicts (psychodynamic), and exploring meaning and ultimate spiritual questions (existential/transpersonal).

Thus, a more comprehensive view of psychological health may best be achieved by honoring the strengths of each tradition, from the biomedical through the transpersonal. It would include the traditional measures such as positive affect, life satisfaction, positive sense of control, self-determination, and self-acceptance. It would also extend the criteria to include sensitivity to the body and its needs (e.g., physical well-being), increased depths of relationship (interpersonal well-being), purpose in life, personal growth, self-actuality, and realizing the limits of ego identity (e.g., existential, spiritual well-being). Clearly, more research is needed to help evolve a systemic, multilevel, and integrative definition of psychological health.

Such knowledge has the potential to considerably augment both clinical practice and even society as a whole.

PSYCHOLOGICAL SCIENCE

Psychological science is concerned with the application of scientific method and principles to the study of a set of questions that traditionally have been categorized as psychological in nature. It also refers to the body of theories and facts about the questions and issues that have emerged from this process. Psychological science is different from mere philosophical speculation about psychological questions. It also is different from the so-called self-help literature that deals in an intuitive way with problems of living. Psychological science requires empirical observation and experimental verification of its speculations, which are often cast as, and considered to be, scientific theories. Defined in this way, psychological science is the discipline of all but a few university departments of psychology.

Because of the development in the past quarter century of the multidisciplinary program called cognitive science, we must make further distinctions. Cognitive science, called the "mind's new science" by Howard Gardner (1985), represents a coalition of approaches that includes aspects of the disciplines of psychology, linguistics, philosophy, neuroscience, computer science, and anthropology. We are, however, faced with a problem: how to differentiate cognitive science from psychological science per se. Pending further developments, for the time being we can conceptualize psychological science as a science dealing with traditionally psychological questions. Psychological science has its own methodology and a philosophy that resists the reduction of psychological questions to brain processes, arguing that such questions must be understood in their own context, on their own terms. Some would argue that psychological processes are based upon emergent properties and functions of the intact functioning organism that require their own set of assumptions and logic. Whether ultimately true or not, such a stance defines a set of issues that can mark off psychological science as a domain separate and distinct from cognitive science.

Psychological questions, at least historically, deal with mental processes and conscious experience or awareness of one's existence and the world in which one exists, a concept that is closely related to mind. Going back to antiquity, humans have speculated about the nature of mind, of the relationship of mind to the world in which they live, of the relationship of mind to the body of which it is a part, of the nature of knowledge and how it is acquired, and of the relationship between mind and human action. Such philosophical speculation constituted a major focus of such notable thinkers as Plato and Aristotle and of a range of philosophers following the Renaissance, including Descartes, Hobbes, Locke, Berkeley, and Kant. Of these, Kant is remembered for his insistence that there could be no science of psychology. This opinion was based on his belief that mental events were not measurable; thus, there could be no mathematical analysis or description of them. Furthermore, according to Kant, mental events were brief and subject to distortion by the observation process itself, and mental events could not be produced by experimental means; they had their own existence and obeyed their own laws and whims. There simply could not be a science dealing with such an unmanageable and even nonphysical subject matter.

The development of psychological science required the emergence of a sophisticated view of science and then a demonstration of the relevance of the scientific method to psychological questions. These requirements seem to have been satisfied around the middle of the nineteenth century, at which time many of Kant's objections appear to have been surmounted by methodological advances leading to pertinent discoveries in physiology. If a date can be provided for the birth of psychological science, perhaps it would be 1874, the year that Wilhelm Wundt's *The Principles of Physiological Psychology* was published. The Preface to this work begins with this remarkable statement: "This book which I here present to the public is an attempt to work out a new domain of science" (p. v).

Both in response to the shortcomings of Wundt's introspective procedure and as a result of early successes in animal psychology, another methodological approach, the behaviorist movement, emerged in the first half of the twentieth century. In part, behaviorism has been seen as an outgrowth of what has been called functionalistic psychology, which is concerned with explaining the function of mind and how mind could be implicated in the coping behavior of humans as well as other animals. But it soon seemed apparent that human and animal behavior could be studied in their own right. The behaviorist approach, as formulated by John B. Watson in 1913, was "a purely objective experimental branch of natural science. . . . Introspection forms no essential part of its methods" (p. 158). Mind and conscious experience were ruled out as topics of scientific investigation because they were not directly observable. Behaviorism, at least in the United States, be-

came a dominant force in psychology and formed the basis for a substantial portion of research publications from 1920 through 1960.

Modern-day cognitive psychology emerged in the 1970s, approximately 100 years after the birth of psychological science, and today is almost synonymous with experimental psychology. Cognitive psychology's subject matter returns to questions of mind, but not in the form conceptualized by Wundt. Rather than examining the nature of conscious experience from the perspective of the observer of that experience, cognitive psychology focuses on theoretical mental processes as they are manifested in observable measures such as accuracy and response time. In this approach, specific characteristics of mental processes are hypothesized and the observable consequences of assumptions about the characteristics are derived. Experiments are then conducted to determine whether or not the hypothesized consequences occur, with a positive result bolstering confidence in the power of the theoretical assumptions. This form of experimentation has as its empirical base observable responses made by the experimental subject, responses that depend on the activities of the hypothesized processes under investigation. From this perspective, cognitive psychology can be viewed as a return to an earlier view about the subject matter of psychological investigation, but with the adoption of the sophisticated and objective methodology of behaviorism. In this view, psychology's focus is not on the structure of conscious experience, but on the task of identifying and explicating the processes that are involved in attention, memory, pattern recognition, linguistic behavior (speaking, listening, and reading), thinking, problem solving, and associated problems.

The history of psychological science from its beginnings in the laboratory of Wundt to the present day reveals a great broadening of its concern. Wundt's experimental procedures were generally limited to the question of identifying the elements of the structure of mind conceptualized as conscious experience. The behavioristic movement substituted a concern with the functioning of animal and human organisms interacting with an environmental context. Present-day cognitive psychology has returned to questions of mental activity, but with a different goal than that of Wundt. Along the way, psychology has adopted a number of methodologies and procedures that extended its scope, and it grew by encompassing a number of areas related to its main goal. Psychology adopted the analytic methodology of statistics and in many areas was able to harness mathematical models to augment its growing methodological armament. The methods and goals of psychological science were applied to a wide variety of psychological questions and in a variety of settings. Today, the introductory textbook in psychology displays a broad array of applications of the methodology of psychological science, ranging from basic subfields of psychology such as perception, learning, cognition, and personality to such topics as drug abuse, mental illness, and gender differences—all areas in which our knowledge has been extended through psychological science.

PSYCHOLOGY AND PHILOSOPHY

Concerns that are now typically part of contemporary psychology—What is the nature of the mind? What causes human happiness? How do humans come to believe or know?—were until the end of the last century part of the concerns of philosophers. In the latter part of the nineteenth century, investigators such as Wilhelm Wundt took an experimental approach to these questions and contemporary psychology was born. Although empirical and experimental methods allow psychologists to address questions commonly outside the scope of philosophy (e.g., What is the incidence of depression?), philosophical concerns continue to influence these empirical pursuits. One clear example of such influence is the general agreement among psychologists that research takes place within a context of philosophical assumptions: What is science? What counts as evidence? What inferences are legitimate to make given the data?

Naturalized Epistemology

Arguably, the central philosophical problem within psychology is the problem of knowledge. Psychologists want to gain and use knowledge, and seek to construct epistemologically sound methods for doing so. Thus, the question "What method(s) can be used to gain knowledge about a particular subject matter?" is of central concern in contemporary psychology. It is central for three reasons: (1) Scientific psychology has made slow progress, and it is difficult not to blame this at least partially on the limitations of its research methods; (2) The phenomena studied by psychologists may be sufficiently different from the phenomena studied by other natural scientists that the wholesale adoption of the methods of natural science for use in psychology may be inappropriate; and (3) Psychology empirically in-

vestigates learning, that is, the acquisition of knowledge, and therefore may inform our conceptions of epistemology. Such approaches to epistemology are referred to as *naturalized* epistemology because they take empirical findings regarding learning into account. Naturalistic approaches to epistemology are endorsed not only by psychologists, but also by prominent philosophers such as W. V. O. Quine and Karl Popper.

The Good Life

Psychologists are increasingly drawn into the domain of ethics, a domain previously relegated to clergy and philosophers. Ethics has to do with the good life, asking questions such as "What is the good?" "How ought I act?" and "Is happiness the ultimate goal in life?" Psychological research, in particular work done by clinical and social psychologists, is viewed by some as providing insight into these important questions. Psychological well-being, for example, is a collection of positive attributes that might be comparable to what philosophers refer to as virtues. Psychologists and philosophers alike agree that variables like good health, positive outlook, quality friends and social network, and a developed sense of self are all implicated in humans' ability to flourish. As with epistemology, there are those who believe that empirical evidence can provide answers to ethical questions. Although most thinkers agree that empirical findings can help people to more effectively realize their goals, it is a matter of great controversy as to whether or not such findings can help to define what is good or virtuous.

Philosophy of Mind

Otherwise known as the mind-body problem, the problematic nature of this field of inquiry is typically traced to Descartes's (in)famous articulation of *substance dualism* (though both Plato and Aristotle weighed in on the issue). Two broadly construed solutions have been proposed to the mind-body problem: *dualism* and *monism*. Though the mind-body problem has changed significantly since Descartes's time, being construed now as the problem of consciousness, the various "solutions" to this problem suggested by thinkers throughout history still address the same fundamental issue.

Substance dualism is the thesis that there is an essential difference between minds (mental phenomena) and bodies (physical phenomena); that is, mind is an essentially thinking substance and body is an essentially extended substance. Given this bifurcation of reality into two separate and unconnected domains, subsequent thinkers have developed theories aimed at ameliorating the difficulties associated with our common sense intuition that the mind and body do, in fact, interact. *Psychophysical interactionism* stipulates that bodily (brain) states cause corresponding mental states which, in turn, are capable of causally instantiating subsequent bodily states. *Epiphenomenalism* is the thesis that bodily (brain) states cause corresponding mental states, but that these mental states are causally inefficacious with respect to bringing about subsequent bodily states. As such, epiphenomenalism is a one-way interaction: body to mind, but not the other way around. *Psychophysical parallelism* avoids the problem of interaction altogether by claiming that mental and physical states run parallel to one another, like two clocks each showing the same time, but do not interact.

Monism is the thesis that all of the objects of reality are of one kind. As such, monism is the explicit denial of the dualistic claim that mind and body are essentially different. Given our predilection toward discussing the topic in terms of the "mental" and the "physical," monistic theories are devoted to describing how one of these terms is reducible, or identical, to the other. *Idealism* is a kind of monism that states "all things are essentially mental or, at least, depend upon the mind for their existence." *Materialism* is a kind of monism that states "all things are physical," that is, the mind is just the brain. *Phenomenalism* is a less popular variety of monism that stipulates that all empirical statements (including, but not limited to, statements about mental and physical states) are reducible to actual or possible phenomenal appearances. In general, any monistic theory that reduces both mind and body to another, more fundamental reality or substance is labeled a *dual aspect theory*.

Free Will and Determinism

As psychological explanations of human behavior become more precise, belief in free will becomes more difficult to entertain. One who maintains that "humans are free agents" claims (at least implicitly) that (1) our psychological understanding of the causes of human behavior underdetermines the actual range and complexity of observed behavior; and (2) no future scientific advances will eventuate in a theory that adequately accounts for the full range of human behavior. Those who adopt a deterministic position need not necessarily claim that current psychological theory does, in fact, account for the entire range of human behavior. Rather, the determinist need only stipulate that such an all-embracing scientific account of human behavior is possible.

William O'Donohue
University of Nevada, Reno

PSYCHOLOGY AND THE LAW

The field of psychology and law began to develop within the last century and is currently in its greatest period of growth and expansion. The interaction between the disciplines of psychology and law has greatly increased over the past few

decades in three overlapping areas: forensic psychology, legal psychology, and psychological jurisprudence. In forensic psychology, psychologists act as experts, practitioners, researchers, and/or consultants with respect to legally relevant clinical areas (such as competency to stand trial, insanity, or civil commitment to psychiatric hospitals). Legal psychology uses applied and empirical research methods to study a range of issues of importance to the legal system (e.g., eyewitness accuracy, police selection, procedural justice, jury decision making, and legal assumptions about human behavior relevant to the rights of defendants, victims, children, and mental patients). Finally, psychological jurisprudence is that area of the field in which efforts to develop a philosophy of law and justice based on psychological values is the main focus.

Evidence of recent growth in psychology and law can be seen in the publication of numerous books and the creation of book series in psychology and law; the creation of journals and periodicals specifically targeted towards psychology and legal issues; the establishment of the American Psychology-Law Society, the American Academy of Forensic Psychology, and the American Board of Forensic Psychology; and the development and expansion of educational and internship experiences. Many graduate programs have developed degree programs in which a specialization or concentration in psychology and law can be obtained, and a number of universities have established joint degree programs in psychology and law in which both a PhD and a law degree are obtained (Bersoff et al., 1999). This article provides a broad overview of the major areas in which psychologists in the field of psychology and law are engaged. Psychologists are often asked to testify in court both about psychological evaluations of individuals and about research findings that may be applicable to a specific criminal or civil court case (see Brodsky, 1999; Ceci & Hembrooke, 1998, for discussion of the role of expert witnesses).

Psychology and law can be conceptualized as encompassing both sides of the justice system (civil and criminal) as well as two broad aspects of psychology (clinical and experimental). Professionals who practice mainly within the civil-clinical area of the field focus on clinical activities within the civil justice system, including conducting evaluations for civil commitment or evaluations of risk for violence among psychiatric patients, or providing psychological treatment for these issues. In addition, researchers working within this area of the field might focus their efforts on developing and evaluating treatment programs or developing and validating assessment instruments to evaluate these civil issues. Professionals who work mainly within the civil-experimental area of the field focus on researching topics at the intersection of psychology and the civil justice system. Examples of such issues include civil commitment criteria, policies, and practices; the right to refuse treatment; and mental health law and policy implications.

Professionals who practice mainly within the criminal-clinical area of the field focus on clinical issues relevant to the criminal justice system and the defendants within this system. Such clinical issues might include evaluations of competency to stand trial, mental state at the time of the offense (insanity), mitigation at sentencing, or risk for future offending, as well as the treatment of offenders (for an overview, see Melton, Petrila, Poythress, & Slobogin, 1997). Researchers within this area of the field might focus on developing and validating instruments for the various types of evaluations or on developing and evaluating treatment programs for various types of offenders or issues (e.g., Heilbrun & Griffin, 1999). Professionals who work mainly in the criminal-experimental area of the field focus on conducting research and advancing knowledge with respect to various aspects of the criminal justice system, such as eyewitness testimony and accuracy, jury deliberations and decision making, police selection, criminal investigation techniques, or punishment and sentencing.

One area that has attracted increased attention in both research and practice is the assessment of violence potential. Research has provided substantial insights into the risk and protective factors that are associated with violent behavior, and this research has changed how we approach risk assessment. Indeed, psychologists have shifted from trying to predict dangerousness to the assessment of risk, which involves thinking about and assessing those factors that will increase or decrease the probability that an individual will become violent in the future. Instead of attempting to make a prediction about a particular individual (and whether he or she is dangerous), the focus changed to an examination of those situational and dispositional factors that would increase or decrease the probability that a particular individual would become violent. Several risk assessment instruments have been developed to guide evaluators through a consideration of particularly important and empirically-derived variables for both adults and juveniles (e.g., Corrado, Roesch, Hart, & Gierowski, 2002; Kropp, Hart, Webster, & Eaves, 1995; Webster, Douglas, Eaves, & Hart, 1997).

The above categorization is, obviously, very broad and simplistic. Many professionals within the field of psychology and law perform multiple activities, which include but are not limited to teaching, research, supervision, expert testimony, consultation, evaluation, and treatment, and which often span more than one of the categories described above.

The discipline of psychology has begun to make an impact upon the discipline of law and continued research and practice is crucial to furthering our understanding of how psychology and the law interact with respect to particular issues. Experts within the field of psychology and law need to continue to conduct research and provide testimony and evidence to help formulate policy recommendations and suggested improvements to the legal systems (both criminal and civil).

The field of psychology and law will, no doubt, continue

to grow and expand in the years to come. It will be important for well-trained professionals to continue to teach, consult, testify, evaluate, treat, supervise, and conduct research in all the various aspects of psychology and law in order to continue to expand and refine this field.

PSYCHOLOGY IN CHINA

Early History

Chinese psychological thought may be traced as far back as 500 B.C. in diverse philosophical, political, and other writings. A distinctive feature of ancient Chinese philosophy was its emphasis on education in cultivating human personality. The great Chinese philosopher Confucius (551–479 B.C.), who had profound influence on the development of China's cultural history, was one of the first scholars to discuss the essence of human nature and how it can be modified through education. Later, Xun Zi (313–328 B.C.) developed a systematic theory of knowledge stressing that the mind is capable of knowing the external world and that human nature can be modified by external influences. These examples indicate the richness of psychological thought embodied in ancient Chinese philosophy. Problems such as the mind-body relationship, the acquisition of knowledge, and the nature-nurture controversy were discussed together with other general philosophical and epistemological issues.

Modern Chinese scientific psychology came into existence after China had more contact with the West. During the first decades of the twentieth century the first group of Chinese students went to Europe and the United States to study psychology, returned to China, and established psychology as an independent scientific discipline. Notably, the famous Chinese educator Cai Yuanpei studied in Wundt's laboratory in Leipzig in 1908, returning to China in 1912. In 1917 Cai became president of Peking University, and with his support the university established the first psychology laboratory in China. During this period psychology was taught in some pedagogical institutions, and many teaching materials were translations from Japanese textbooks. In 1921 the Chinese Psychological Society was founded, and the first psychology journal appeared in 1922. With the introduction of the Western educational system into China, psychology expanded rapidly.

In 1937, the Japanese invasion of China resulted in the occupation of a large part of China, causing serious setbacks in the progress of psychology. The occupation lasted until the end of World War II.

Psychology After the Founding of the People's Republic of China

The People's Republic of China was founded in 1949. Chinese psychologists started a movement for reform and independence from Western influences. The new psychology took Marxist philosophy as its guiding principle; psychology in the then-Soviet Union was looked upon as the model. During this period, social psychology and psychological testing were abolished on the grounds that the former ignored the class nature of society, and the latter favored the selection of children of the elite class into schools. Following the educational system in the Soviet Union, there were no independent departments of psychology in Chinese universities. Psychology was a secondary discipline in the departments of philosophy or education.

After 1949, psychology was frequently attacked by leftist political ideologists as an imported Western bourgeois ideology, the mouthpiece of capitalistic individualism. Crit-

ics argued that many psychological experiments conducted in the laboratory failed to reflect real-life situations. These attacks on psychology set the stage for the liquidation of psychology between 1966 and 1976, the period of the well-known Cultural Revolution. This time psychology was uprooted completely as a scientific discipline. Scientific research and teaching institutions in psychology were dissolved, and psychologists were dispatched to the countryside to work on the farms. The Cultural Revolution ended in 1976.

Recent Developments

From 1978 on, the Chinese government launched a policy of reform and opening up to the outside world. The change has pushed Chinese psychology into a new era of development. There are now more than 30 departments of psychology in Chinese universities, and the Chinese Psychological Society now has about 5,000 members. Chinese psychology has since moved into the international community. The Chinese Psychological Society joined the International Union of Psychological Science (IUPsyS) in 1980. Many exchanges were established between Chinese universities and universities in other countries.

As experimental psychology has become less affected by ideology, cognitive theory has penetrated into many fields of psychology. Basic research in cognitive processes has increased, and studies of perception, memory, and learning have attracted consistent interest. The Chinese language, as an ideographic language with a unique writing and structural system, has attracted much attention in attempts to understand its acquisition and learning processes. Studies have included the ideographic and sound characteristics of Chinese characters, their reading and comprehension, and the hemispheric laterality of information processing of Chinese language. Exciting findings have been reported in this field.

Neuropsychology is also a field of interest; studies have included the neural mechanism of memory, memory changes in aging, the effects of drugs on behavior, and psychoimmunology. Recently, studies have been made using Positron Emission Tomography and Functional Magnetic Resonance Imaging on basic cognitive functioning.

The areas of developmental and educational psychology have always been lively fields of research in China. There are 300 million children in China, and any new knowledge in this field would have implications for the cultivation of an entire generation. About half of the 5,000 Chinese psychologists now work in teacher training universities or pedagogical institutes. The Ministry of Education in China is advocating a Quality-Oriented Education program to give children a comprehensive education—morally, intellectually, physically, and aesthetically. Such an education is achieved by improving teaching methods, revising curriculum arrangement, stressing moral education, and requiring students to participate in social activities.

Psychologists also work in other practical fields in which psychology can make effective contributions to society. Health psychology and psychological counseling are becoming popular in China. A large number of counseling centers have been established in schools and social institutions. Personnel selection and human resource evaluation centers have been set up to aid in the selection of government employees and workers in industrial and commercial enterprises. Other newly developed applied fields are industrial psychology and managerial psychology. The economic reform of China calls for the introduction of new methods of management in industrial enterprises. Incentives and motivational studies have been carried out to promote efficiency. Managerial assessment methods are being introduced from Western countries and adapted for domestic use.

Psychology in China, after having undergone full-fledged development for only 30 years after the Cultural Revolution, has developed into a mature scientific discipline able to serve society in both its basic and its applied fields.

PSYCHOLOGY IN GERMANY

In the first third of the twentieth century, Germany was among the leading nations in scientific psychology, and German was an important language for psychological publications. Today, the impact of German psychology on the scientific community is rather small (Keul, Gigerenzer & Stroebe, 1993; Montada, Becker, Schoepflin, & Baltes, 1995). First, we will discuss reasons for the decline of German psychology. Second, we will outline the status of today's German psychology.

Decline of Psychology in Germany

The obvious reason for the decline of German psychology was the Nazi regime (1933–1945). Most eminent psychologists, mainly Jews, were harassed, fired, and either emigrated, committed suicide, or were killed. In all, 130 psychologists from German universities emigrated, including

29 full professors (Geuter, 1986), and after the war, only a few (14 according to Geuter, 1986; e.g., Bondy and Düker) returned. Simultaneously, 79 psychology professors employed at the German universities during the Nazi regime remained in their positions after 1945 (Geuter, 1986), in spite of the fact that most of them received their positions for political reasons and not because of scientific excellence.

A first restructuring of the German university system and psychology was triggered by the student revolts of 1968. German universities became open to a larger number of students, and the number of employed scientists in psychology increased about tenfold. However, only a few well-trained and internationally competitive psychologists worked in Germany, Austria, or Switzerland. As a consequence, the scientific output and the international reputation of German psychology did not substantially improve.

German Psychology Today

In Germany today about 50 university departments or institutes of psychology exist, with somewhat more than 400 professors (full professors and "habilitierte" associate professors) holding research and teaching positions. In addition, there are about 30 departments or institutes of medical psychology, with about 90 professors. The curriculum is tightly regulated by nationwide study and examination guidelines, and therefore universities do not greatly differ in teaching and examination topics. Distribution of students to universities is regulated by a national agency on the basis of pre-university grades. Since there are far more applicants to study psychology than available openings, this nationwide selection process gives universities and professors no opportunity to select students, and does not allow students to choose departments with proven excellence. As a consequence, competition between universities for students and state money until now has been weak. Only recently, rankings (although of questionable validity) for universities and study subjects were published, and only recently did states begin to distribute modest amounts of research money on the basis of proven scientific scholarship.

Most recent reviews conclude that the research resources for psychology in Germany are comparable to or even better than those in the United States, Britain, Canada, Australia, France, the Netherlands, or Israel. However, the scientific output, the international reputation, and the reception of German psychology were found to be mediocre. For example:

- Physics and chemistry in Germany contribute about 3 to 4% of the publication in international journals, while the corresponding number for psychology is below 0.5%.
- 42% of the German professors in psychology did not publish within a five-year period (1986–1990) any article which was listed in the SSCI (Keul et al., 1993).
- A considerable number of German psychologists never or rarely publish in English (Basler & Schieferbein, 1995; Keul et al., 1993; Montada et al., 1995). However, it is now recognized that publications in German have a 5 to 10 times lower citation rate than publications in English.
- An evaluation of *Psychological Review* and *Psychological Bulletin* articles between 1975 and 1992 revealed that German contributions are rare, comparable with the Netherlands, Israel, and Sweden, although these countries all have substantially smaller populations, fewer full professorships, and fewer research resources (Keul et al., 1993). In addition, most publications of German psychologists in APA journals come from a few institutes (Montada et al., 1995).

These problems are mainly acknowledged now, and several proposals have suggested ways of improving scientific output, as well as international reception and citation of German psychology (e.g., Gigerenzer et al., 1999).

The slow but continuous increase in the proportion of publications in international journals by German psychologists, mainly driven by a subgroup of productive psychologists, indicates progress (Becker, 1994). German psychophysiologists and social psychologists in particular have received international acknowledgement in their fields (Keul et al., 1993).

An asset of the German science system that greatly helped to overcome the decline of psychology in Germany after the war and to improve the reputation of German psychology is the German Research Foundation (DFG, Deutsche Forschungsgemeinschaft). Based on the lessons learned during the Nazi regime, the peer review process and the rules for grant applications do not allow any political or economic influences or pressures. Grant award decisions are based only on peer review and scientific reputation. The grant money awarded to psychology has continuously increased within the last few years, a sign that the quality and international reputation of psychology in Germany is improving.

PSYCHOLOGY IN ICELAND

Psychologists in Iceland have been trained in various countries. An undergraduate course in psychology was started at the University of Iceland in 1971, but postgraduate training in psychology had to take place abroad until 1999, when a postgraduate MA course in psychology began at the University of Iceland. Initially most Icelandic psychologists completed their training in Denmark, but later they sought their training in other countries (e.g., Norway, Sweden, Germany, France, England, Scotland, United States, Canada, Australia).

The Icelandic Psychological Association (IPA) was established in 1954, and the current membership is 177. Within the association there are three divisions: clinical, educational, and rehabilitation psychology. The office of the IPA is housed at the Academics Union Bandalag Hàskòlamanna (BHM).

The profession of psychology in Iceland is regulated by law #40/1976, which protects the title and to some extent the function of psychologists. The accrediting committee of the Icelandic Psychological Society is consulted by the Ministry of Health, which is the awarding authority of accreditation for psychologists in Iceland. Only those who have the right to call themselves psychologists can apply for positions advertised for psychologists. Psychologists are permitted to practice psychotherapy.

Four specialties are recognized within psychology in Iceland and regulated by bylaw #158/1990: clinical psychology, rehabilitation psychology, educational psychology, and organizational/occupational psychology. Only those who have been accredited by the Ministry of Health to practice as psychologists can embark upon postgraduate training in one of these specialties; this training lasts 4½ years. During this time the trainee has to work under the supervision of a specialist within specified areas for a stipulated number of months. The trainee receives 120 hours of personal supervision from at least two specialists and 40 hours of group supervision (1 hour per week/40 hours per year). The trainee has to complete 300 hours of didactic training. Finally, the trainee has to conduct a research project and publish in a refereed journal before becoming recognized as a specialist in one of the areas above.

Most of the psychologists in Iceland are employed by health, social, and school services. There are about 10 psychologists working full time and about 30 part time in private practice. The services rendered by psychologists and specialists in psychology in private practice are not reimbursed by the national health services, private insurance, or the social services. Patients are either self-referred or referred by a physician or the social services. Many practicing psychologists consult with corporations and industry.

PSYCHOLOGY IN SPAIN

Despite the fact that the history of Spanish psychology shows a marked lack of continuity, it is possible to pinpoint a number of outstanding figures whose work achieved international dimensions.

Juan Luis Vives (1492–1540), born in Valencia in the year in which Columbus first stepped foot on American soil, attempted to focus his contemporaries' attention on the direct observation of human behavior rather than on such indefinable concepts as the soul or the mind. Vives constantly stressed the need for making the most of direct experience as the most reliable source of knowledge.

Juan Huarte de San Juan (1529–1588) in his book, *Examen De Ingenios Para las Ciencias,* presented an ingenious theory about the relationship between psychology and physiology, explaining how good vocational guidance can be built upon this relationship. Apart from its interest as a pioneer attempt in the field of applied psychology, the book is also worth mentioning for its determinist stand, its incipient evolutionism, and the importance it places on the influence of environmental factors.

Santiago Ramón y Cajal (1852–1934), is credited with theories and discoveries on nerve cells and synapse that paved the way for a considerable amount of research work in psychophysiology. Emilio Mira y López (1896–1964) was probably the first Spanish-speaking psychologist to show an interest in behaviorism, and one of the first to study the

work of Sigmund Freud. His published writings include works on psychoanalysis, legal psychology, psychiatry, evolutive psychology, vocational guidance, and experimental psychology.

Ramón Turró (1854–1926), undertook the forceful defense of the experimental method, personifying the spirit of Claude Bernard in the mentalist scene that prevailed in Spain at the turn of the century. A great admirer of Ivan P. Pavlov, Turró pursued some interesting experiments with newly born animals to determine how they learn their first specific responses as a basis for all later knowledge. Turró's standpoint on many subjects was truly original.

International psychological trends found their way into Spain, and were welcome there, but with different degrees of success.

One of the key figures in introducing scientific psychology into Spain was Luis Simarro (1851–1921). A member of the Institución Libre de Enseñanza, a movement that attempted the political and social renewal of Spain through the renewal of its educational system.

The phenomenology and Gestalt movements found their way into Spain a little later, thanks to people such as José Ortega y Gasset (1883–1955), who tried to open the country to the trends in psychology and philosophy that appeared in Europe after Wundt. About the same time, the "Geneva School" also started to show its influence in the country, an influence still noticeable today.

In 1917, following ideas advanced in Germany by Hugo Münsterberg in 1911, an Instituto de Orientación Profesional (Institute for Vocational Guidance) was established in Barcelona. This was one of the first centers of applied psychology in the world. Mira y López was elected to head the Institute.

José Germain had studied with Claparède in Geneva, with Wolfgang Köhler in Berlin, and with Pierre Janet in Paris. After the Civil War, he helped to bridge the gap between the postwar generations and the scientific psychology that was trying to become established in Spain in the early 1930s. In 1948, the Consejo Superior de Investigaciones Científicas (Higher Council of Scientific Research) founded the Department of Experimental Psychology with Germain as principal. Among those who worked for the Department were Pinillos, Siguán and Yela. Some years later, they were to be the first professors of psychology in Spanish universities in charge of establishing the systematic study of psychology.

In 1953, the Escuela de Psicología y Psicotecnia de la Universidad de Madrid (Madrid University's School of Psychology and Psychotechnics) was inaugurated. The first attempt to establish university studies of a purely psychological nature, this school was open only to postgraduate students. In 1964, a similar center was set up in Barcelona. Eventually, in 1968, the universities of Madrid and Barcelona began to offer five-year courses in psychology for undergraduates. Their example was soon followed by the remaining Spanish universities.

The last 20 years have been marked by a considerable expansion in Spanish psychology. By the end of the twentieth century there will be more than 30,000 licenced psychologists in the country. The fields of research and application have expanded from health psychology and sports psychology to forensic psychology and traffic psychology. Interdisciplinary areas, such as psycho-oncology and psychoneuroimmunology, are also developing and, in a growing number of hospitals, psychologists are included in palliative care teams. Spanish psychologists are now working on topics such as adherence to new AIDS antiretroviric drugs, anorexia and bulimia, addictive behaviors, counseling, burnout, and so on.

R. Bayés

PSYCHOLOGY OF MEN

The study of sex and gender differences in psychology has a long and distinguished history. However, a field of psychology explicitly and intentionally devoted to the study of the psychology of men is a relatively recent development. Beginning as a response to the feminist critique of traditional gender roles that gained prominence in the late 1960s, the psychology of men has blossomed into a prominent specialization within developmental, clinical, and counseling psychology. The American Psychological Association has established a division, The Society for the Psychological Study of Men and Masculinity, devoted to the psychology of men. In addition, a number of national organizations, such as the National Organization of Men Against Sexism, have sections and interest groups devoted to issues pertaining to the psychology of men.

The psychology of men traces its roots to the feminist analysis of traditional gender roles. Social scientists and psychologists interested in the psychology of men followed the lead of feminist researchers and studied the restrictive and detrimental effects of male gender role socialization. Some of these effects included difficulties in intimate emotional relationships, inhibitions on male-male friendships, restriction of emotional expression, excessive devotion to work and competition, drug and alcohol problems, and interpersonal violence.

In institutions of higher education, psychologists studied restrictive gender role socialization as it related to both men and women. As these researchers disseminated their findings through conferences and publications, a subarea of gender psychology devoted to the psychology of men began to develop. Psychologists working in this area began to build scientific support for feminist-inspired critiques of traditional gender roles as applied to boys and men. The development and use of psychological assessment instruments to measure the negative impact of this restrictive

masculine gender role socialization further enhanced the scientific credibility of the emerging field of the psychology of men.

Scholars studying the psychology of men have documented the existence of psychological stress associated with adherence to traditional masculine gender roles. Historically, traditional masculine gender roles have been defined as an overvaluing of competition and toughness, a devaluing of emotional expression, and an aversion to behaviors and activities associated with femininity. Research demonstrated that attempts by men to adhere to these aspects of the masculine gender role were associated with restricted emotional expression, value conflicts between occupational or vocational achievement and devotion to family, inhibitions on affection between men, and excessive preoccupation with power, competition, and control. Men who experienced conflict in these aspects of their lives also experienced increased levels of stress, anxiety, depression, physical problems, and a host of other detrimental psychological symptoms.

As academic psychologists researched aspects of strain associated with adherence to the traditional masculine gender role, practicing psychologists began to develop networks of men and women who were devoted to challenging the social problems that resulted from such adherence. At least three distinct men's movements emerged from these efforts. First, a movement called the mythopoetic men's movement, spearheaded by the poet Robert Bly, was marked by the publication of his popular book *Iron John* in 1990. This movement was devoted to supporting men as they examined the personal meaning of masculinity in their lives. This movement utilized a number of different venues to achieve its goals, including workshop formats, weekend retreats, individual psychotherapy, and at times men's counseling groups specifically dedicated to this endeavor. A second men's movement, called the men's rights movement, emerged from networks of men working together to fight what were perceived to be inequities in the judicial system. Problems that some men associated with divorce or child custody proceedings were an impetus for the advancement of the men's rights movement. Finally, the profeminist men's movement was organized to address issues of social justice that were largely based on feminist critiques of American culture. Aspects of these critiques include the discrepancy in pay between women and men, violence directed toward women by men, and other aspects of oppression perceived to be a result of traditional masculine ideology and socialization.

Today, researchers in the psychology of men have extended their inquiry into specific problem areas for men, such as male depression, violence, suicide, and men's health problems. In addition, a number of psychologists are examining why boys tend to perform poorly in school settings, and why boys are more frequently diagnosed with behavior and learning problems in these settings. Research has demonstrated that over the span of a typical educational experience, boys tend to perform much more poorly than girls on a number of achievement and outcome measures.

In addition, a number of clinical and counseling psychologists have been developing specific assessment and intervention methods geared toward helping male clients in educational, hospital, and clinic settings. Some of these methods include the use of all-male psychotherapy groups and masculine-specific counseling and therapy methods designed to reduce the stigma many men feel when they seek help for personal problems. An important benefit of such efforts may be that more men will seek help for the stresses associated with efforts to conform to the traditional masculine gender role.

University of Iowa

PSYCHOMETRICS

The field of psychometrics generally considers quantitative psychological data. Such data normally emerges from test responses, although it may come from other measures. Psychometric theory (e.g., Nunnally, 1978; Lord, 1980) provides mathematical models for considering responses to test items, tests, and sets of tests. Applied psychometrics implements these models and applies their analytic procedures to test data (e.g., Thorndike, 1982). Four concerns of psychometrics include norming and equating, reliability, validity, and item analysis. There are both theoretical formulations for each of these four categories and actual procedures to be performed in estimating the usefulness of a test in a specific instance.

Norming and Equating

Norming and equating procedures are used in developing test score reporting systems. Norming is part of test standardization and involves administering the examination to a representative sample of individuals, determining various levels of test performance, and translating raw test scores to a common metric. There are two scoring models: linear and nonlinear transformations. Linear transformations change the mean and standard deviation of the raw test scores, but maintain all other aspects of the raw score distribution; the relative positions of examinees are unchanged. The purpose of linear transformations is to provide test results on scales with which test users are familiar, and hence to increase the amount of information and meaning carried in a score.

Three nonlinear transformations are common: normalization transformations, percentile equivalents, and developmental norms. Normalization transformations fit the test score distribution to a normal curve while maintaining

the original rank-ordering of the examinees. Percentile equivalents express each score as the proportion of examinees falling at or below that score. Developmental norms are converted scores that express test performance relative to normal development, typically either years of age or schooling. Age equivalents such as mental age describe test performance in terms of behavior typical for children of various ages. Age and grade equivalent scores are often used, but have extreme psychometric and interpretative problems (Anastasi & Urbina, 1997; Thorndike, 1982).

When there are numerous forms of the test, tests are normally equated. While all forms should measure the attribute with equal precision, raw scores from different forms customarily have varying percentile equivalents. Equating brings forms to a common scale (see Kolen & Brennan, 1995). Angoff (1971) and Thorndike (1982) also describe equating methods.

The past 30 years have led to a family of models of test scores called item response models (IRT). These models permit scaling of tests and test items using methods presumably independent of the population from which the test data emerge, and are explained by Hambleton, Swaminathan, and Rogers (1991); Lord (1980); and Thorndike (1982).

Reliability

Both reliability and validity refer to the generalizability of test scores—assessing the reasonableness of inferences about test scores (Cronbach, Gleser, Nanda, & Rajaratnam, 1972). Reliability concerns inferences made about consistency of measurement. Consistency is defined by tradition as a family of relationships: temporal stability, comparability of tests proposed to be equivalent, homogeneity within a single test, and comparability of judgment-based assessments made by raters. A procedure called the "test-retest" method is used to establish the reliability of a test by administering the test and then waiting a short period (e.g., 2 weeks) before administering the same test again to the same group. In the alternate-forms method, multiple parallel measures are developed and both are administered to a sample of examinees. Both of the above methods use the correlation coefficient between the two sets of measurements as the reliability coefficient, an index that ranges from 0.00 to 1.00 and denotes the percentage of test variance that is reliable. Using raters essentially as parallel forms is called inter-rater reliability and is often used when expert judgments are needed.

Each of the above procedures flows from what has been called the classical or parallel testing model of reliability (Campbell, 1976; Nunnally, 1978). In this model, each test score is perceived as the sum of two independent components: true score and error. True scores may be thought of either as perfect measurement of the attribute in question, were such assessment possible, or as the average of an infinite number of testings. Error is defined as randomly occurring deviations from the true score. Under these conditions, it follows that when two sets of purportedly parallel measurements are correlated with one another, the resultant correlation coefficient is equal to the proportion of the individual differences resulting from the test that are due to true score differences—statistically, the ratio of true score variance to the variance of obtained scores.

An alternate model to the parallel testing model is the domain sampling model. This model requires that a test constructor define the universe of behaviors of interest. Reliability is defined as the ability of the given test to predict an individual's score on all tests in that universe. Among the reliability estimation procedures that emanate from this model are various internal consistency formulations that estimate the correlation between the test and the universe from the average correlations between items on the test.

A third model, the generalizability model (Cronbach et al., 1972; Stanley, 1971) goes a step beyond the domain sampling model; it assumes that one may generalize over dissimilar conditions as well as similar conditions. Thus, in the domain sampling model, a researcher may estimate the reliability between two PhD-level psychologists, whereas in the generalizability model, one could estimate the extent to which one may generalize from a PhD-level psychologist to another professional. One can generalize from one set of scores or observations to others collected at another time or under somewhat different conditions, for instance. Generalizability bridges the gap between reliability and validity.

Validity

Validity refers to the quality with which a measurement procedure permits the desired inferences. Because psychologists make a number of different kinds of inferences using tests and measurements, there have traditionally been several kinds of validity: predictive validity, content validity, and construct validity. Predictive validity has been used to assess the ability of measurement devices to infer success on the job or in advanced education. Typically, the predictive measure is correlated with some quantified assessment of job or school success, called a criterion. Thus, tests used for admission to graduate or profession schools are frequently correlated with grades at that school. The resultant correlation coefficient is called the validity coefficient. Furthermore, because a single instrument is often not able to predict a criterion as well as would be desired, multiple predictors are used, often with the statistical procedure of multiple regression. This procedure weights the various predictive tests to achieve maximal prediction of the criterion. A methodology has also been developed to insure that predictions from tests do not favor one group or discriminate against another. In general, findings of such "differential validity" have been quite rare.

When the purpose of a test is to assess mastery of skills within some behavioral domain, content validity is often involved. The content validity of a test is typically judged by

determining how well the domain has been covered. Those who are expert in the test domain generally make such judgments. Careful and detailed description of the domain prior to test construction and implementation of procedures to insure adequate sampling from all aspects of the domain are critical for content validity.

In recent years, it has become accepted that construct validity subsumes predictive and content validity (Geisinger, 1992; Messick, 1989). The critical question asked with regard to construct validity is how well a given test measures the trait(s) it is supposed to be measuring. The construct validity of a test is rarely determined by a single study; rather, it is the gradual accumulation of evidence that provides conclusions regarding construct validity. Procedures implemented to insure content validity and predictive validity research may be used as part of the evidence needed for the construct validation of an instrument. Anastasi & Urbina (1997) provide a good introduction to construct validity and Messick (1989) offers a rather complete summarization.

One key part of validity, as acknowledged by many test theorists (e.g., Messick, 1989), relates to test fairness. If a test is valid, then it should not lead to scores that differ inappropriately among groups as divided by various racial, ethnic, or gender lines, among others. Considerable effort has been put forth over the past 25 years to help psychologists and others develop and use psychological measures fairly (Sandoval, Frisby, Geisinger, Scheunemann, & Grenier, 1998).

Item Analysis

Item analysis procedures are generally employed in test construction and refinement with the purpose of selecting items to maximize a test's utility. Descriptions of the techniques overviewed here may be found in Henrysson (1971) or Thorndike (1982). Most item analysis procedures either (1) look at the number of examinees answering the item correctly and incorrectly, (2) correlate individual items with other variables, or (3) check items for bias.

Conclusion

This article has of necessity omitted numerical concepts, but psychometrics is a quantitative discipline, as perusing the references will demonstrate. The aim of the four quantitative concepts presented in this entry is to improve the quality of data in psychology. The use of norms make test scores communicate information more effectively; equating tests makes scores from varying forms of the same examination comparable. In general, the value of any psychological measuring device is defined by its validity, and the reliability of a measurement procedure limits the validity of the device (i.e., when individual differences on a test are due to random fluctuation, any correlations with that instrument would generally be considered to be randomly based as well). Thus, psychometrics is a discipline that employs numbers, but it is also a discipline that evaluates itself quantitatively.

PSYCHONEUROENDOCRINOLOGY

Psychoneuroendocrinology is the study of endocrine functions ultimately controlled by the brain. In turn, many brain processes underlying mood and cognition are influ-

enced by the hormonal products of the various endocrine organs. The main endocrine functions of the body organize development and growth, reproduction, homeostatis (temperature, fluids, minerals, and energy balance), and immunity. Although endocrine dysfunctions are often produced by direct organic disorders, many endocrine disorders have been traced to abnormal brain processes. Thus, the discipline of psychoneuroendocrinology focuses on an exploration of the relationships between mind, brain, and endocrine systems. The following account briefly describes the major constituents of the neuroendocrine systems, and focuses on how the brain, moods, and cognition regulate, and are regulated by, hormones.

General Principles

Most vital endocrine functions in humans are directly influenced by a relatively small brain region—the hypothalamus (roughly 0.003% of the entire brain mass). The neurosecretory cells that regulate the garden pea-sized pituitary (*master*) gland at the base of the brain are located in the middle third of the hypothalamus. The important neuroendocrine cell groups in this region consist of the paraventricular and arcuate nuclei. Different groups of cells in these nuclei are responsible for the direct release of some hormones in the bloodstream. These hypothalamic influences are mediated by direct axonal projections through the *infundibular stalk* to the *posterior lobe* of the pituitary. They control functions such as water balance through the release of antidiuretic hormone (vasopressin), and control uterine contraction and milk-production/ejection in pregnant and lactating women, respectively, through the release of the hormone oxytocin.

However, the majority of tropic hormones are synthesized and released by the *anterior lobe* of the pituitary, through the secretion of special hypothalamic peptides termed *releasing factors*. Upon their secretion, these releasing hormones enter capillaries at the level of the *median eminence* that coalesce to form *portal vessels* that run through the infundibular stalk and terminate in vascular sinuses in the anterior lobe of the pituitary. The range of functions associated with anterior pituitary hormones includes maturation and growth, immunity, stress responsivity reproduction, energy, and metabolism, broadly defined. Thus, although the pituitary gland is responsible for the release of many hormones acting on body tissues and end-organs, it is admirably enslaved by the hypothalamus, and by *negative feedback* effects of the released hormones. Negative feedback inhibition is an important regulatory mechanism whereby hormone release acts at several levels, including the pituitary, hypothalamus, and even brain areas that project to the hypothalamus, to reduce its own further release and thus help reduce deviations from optimal set points that are detrimental to organisms. The hypothalamus and the brain circuits associated with its activity play a critical role in endocrine functions, and, in turn, endocrine status has a significant impact on brain processes subserving affect and cognition.

Hormones, Mood, and Cognition

Most hormones play a significant role in affect and cognition. An example is cortisol, which is secreted by the adrenal cortex under the influence of the anterior pituitary peptide adrenocorticotropin hormone (ACTH). Cortisol hypersecretion, such as in Cushing's disease, produces psychological changes ranging from hyperphagia, insomnia, and euphoria to anxiety, panic, and mania. On the other hand, a significant number of individuals diagnosed with major depression present signs of adrenal hypertrophy and increased circulating levels of cortisol. The mechanisms hypothesized to mediate increased cortisol levels in clinically depressed patients have implicated increased activity at the level of the hypothalamus, and dysregulation of brain serotonergic and noradrenergic systems. A *reduction* of circulating cortisol levels, observed in patients with Addison's disease (adrenal atrophy and insufficiency), is itself correlated with irritability, apprehension, mild anxiety, and inability to concentrate. Thus, low or high circulating cortisol levels produce psychiatric symptoms.

The mechanisms whereby low cortisol levels affect mood and other cognitive functions are poorly understood. Normalization of cortisol levels usually improves the psychological profiles of these patients, and a variety of antidepressant treatments also lead to cortisol normalization in depressed patients. Learning is also influenced by circulating cortisol levels and evidence of poor memory with either too much or too little cortisol has been documented.

Similar observations are reported with thyroid hormones (T_3 and T_4), which are crucial for normal brain development and function. Hypothyroidism during fetal life (a condition known as *cretinism*) produces short stature, sexual immaturity, and severe mental defects in afflicted individuals. In adulthood, hypothyroidism is often associated with depression, bipolar disorder, low energy, appetite and sleep changes, poor concentration, memory impairments, and apathy. The similarity of these symptoms with clinical depression routinely prompts clinicians to test thyroid functions to distinguish between the two conditions. The reverse interaction between affective illnesses, particularly major depression, and thyroid hypofunction has also been documented recently. As with cortisol, hyperthyroidism (as in Grave's disease) presents with several psychiatric symptoms including insomnia, irritability, agitation, major depression, Attention-Deficit/Hyperactivity Disorder, paranoia, and most often, Generalized Anxiety Disorder. Exactly how thyroid hormone dysregulation produces affective disorders, particularly major depression and rapid-cycling bipolar disorder, is mostly unknown. Lower thyroid hormone levels have been suggested to reduce β-adrenergic receptor activity and central serotonin activity, states often associated with a variety of affective disorders.

Growth hormone (GH—also known as somatotropin) dysregulation similarly has a variety of interactions with affect and cognition. Perhaps the most famous phenomenon associated with GH hyposecretion in children is psychosocial dwarfism, a state of short stature sustained by parental abuse. GH deficiency in adults is associated with higher incidence of affective disorders, lack of energy, and impaired self-control. GH hypersecretion can also result in affective disorders, increased appetite, and loss of drive and libido, without observable changes in intelligence or memory functions. Treatments that normalize GH levels ameliorate the psychologic symptoms produced by GH dysregulation. A similar picture emerges with sex hormones, which are believed to be responsible for disturbances in memory retrieval, anger, moodiness, and anxiety associated with premenstrual syndrome (PMS) in 30% of cycling women, and perhaps some cases of major depression associated with childbirth and menopause. Elimination of ovarian cycling in PMS, or estrogen replacement at menopause, can be effective treatments for these conditions. On the other hand, several affective illnesses, as well as physical and psychological stress, are well known to interfere with sexual functions in general and with their associated hormones and cycles.

There are thus clear psychological outcomes associated with endocrine imbalances, most of which are ameliorated with hormonal normalization. Likewise, psychiatric conditions encompassing several mood disorders have a significant impact on most endocrine functions. These observations suggest a close connection between the brain substrates underlying affect and the control of endocrine systems, a connection that essentially remains to be uncovered.

PSYCHONEUROIMMUNOLOGY

Psychoneuroimmunology (PNI) is the study of behavioral-neural-endocrine-immune system interactions. It emerged from the realization that the immune system does not operate autonomously, as had been assumed by those who conceptualized it as a closed system, driven by challenges from foreign substances (*antigens*), and regulated by soluble products produced and released by immune cells (e.g., lymphokines, cytokines, monokines). Although antigens do initiate immune responses, and cytokines (such as interleukin-1) do regulate immune processes, data now demonstrate that there are *bidirectional communication pathways* between the immune system and central nervous system (CNS), with each providing important regulatory control over the other (Maier, Watkins, & Fleshner, 1994). The general function of the immune system is to identify and eliminate antigens that enter the body, such as pathogenic microorganisms (bacteria, viruses), fungi, parasites, tumors, and toxic chemicals. It also acts as a regulatory, repair, and surveillance infrastructure, preventing its components from turning against each other and assisting in tissue repair after injury.

The most important cells in the immune system are the thymus (or T) cells, and the leukocytes or white blood cells, of which there are three major categories: granulocyte cells, monocytes (called macrophages when they mature), and lymphocytes—bone marrow (or B) cells, responsible for the production and secretion of antibodies. There are three general types of T cells: Cytotoxic T cells are capable of destroying target cells; natural killer (NK) cells destroy virally infected cells and certain tumors; and helper T cells enhance the immune response. The latter cells are the primary targets of the human immunodeficiency virus (HIV).

Immune function can require global alterations involving the entire organism as well as local processes, and only the CNS can orchestrate such widespread outcomes in a coordinated fashion. Thus, the CNS must be able to exert control over some aspects of the immune response. Conversely, in order to accomplish this function, the CNS must receive information about events in the body, such as infectious agents that have penetrated the skin, and the status of the

immune processes. Hence, the immune system exerts control over neural function, and the CNS exerts control over the immune system. These neural-immune interactions permit psychological events to enter the matrix; if neural processes regulate immune processes, then potentially they can impact behavior, emotion, and cognition. PNI studies these complex interactions.

One branch of the immune system can be referred to as the *antibody-mediated subsystem,* which operates through the bloodstream by means of antibodies produced by B cells. When activated by an antigen, B cells produce any of five known types of antibodies; for example, type IgE tends to increase during stress and is responsible for allergic reactions (e.g., wheezing and sneezing as reactions to pollen or house dust). The action of B cells in the antibody-mediated subsystem is influenced by T cells and macrophages, which belong to the immune system's other branch, *the cell-mediated subsystem.* They produce "messenger" substances (e.g., cytokines, lymphokines, monokines) that impact other immune cells. A tumor cell can be attacked by macrophages after being covered with antibodies, or can be killed directly by NK cells. Helper T cells facilitate the function of the killer T cells and the B cells; as a result, innate immune mechanisms operate as a first line of defense against invading pathogens. In addition, the immune system is influenced by neuroendrocrine outflow from the pituitary gland. Two pathways link the brain and the immune system: the autonomic nervous system (ANS) and neuroendrocrine outflow by way of the pituitary. Both routes provide biologically active molecules capable of interacting with cells of the immune system. The potential interactions between neuroendocrine and immune processes is shown by observations that immune cells activated by immunogenic stimuli are capable of producing neuropeptides (Ader, Cohen, & Feltin, 1995).

A laboratory example of CNS involvement in the modulation of immunity is the classical Pavlovian conditioning of antibody- and cell-mediated immune responses. When a distinctly flavored drinking solution (the conditioned stimulus) is paired with injection of an immunosuppressive drug (the unconditioned stimulus), the subsequent antibody response is attentuated in conditioned animals reexposed to the conditioned stimulus (Ader & Cohen, 1991). In Pavlovian terms, an antigen can be thought of as an unconditioned stimulus that elicits an immune response. These data may assist the understanding of how immune activity can decrease as a result of exposure to stimuli that are not ordinarily immnosuppressive. For example, women who had undergone a number of chemotherapy treatments for ovarian cancer displayed immunosuppression after simply returning to the hospital for additional treatment.

When a transplant reaction occurs, it is a result of the cell-mediated immune response. Cell-mediated immunity is also responsible for delayed types of allergy or hypersensitivity. A person sensitive to tuberculin as a result of exposure to tuberculosis will develop an area of reddening and hardness of the skin shortly after the injection within the skin. PNI studies also implicate psychosocial factors in the predisposition to, and the initiation and progression of, diseases involving somatization (Wickramasekera, 1998). The chain of psychophysiological events has not been firmly established, but changes in several components of both antibody- and cell-mediated immunity have been associated with naturally occurring and experimentally induced behavioral and emotional states. For example, the degree of students' loneliness can moderate their immune reactions (Kiecolt-Glaser, 1999).

PNI has triggered a paradigm shift in the understanding of immunoregulatory functions. This new paradigm may provide an understanding of the means by which psychosocial factors and emotional states influence the development and progression of infectious autoimmune and neoplastic diseases. However, most studies have examined only one measure of immunity at one point in time with a circumscribed sample. It will take a considerable amount of research to distill general principles from these specific findings.

PSYCHOPATHIC PERSONALITY

The Antisocial Personalities

The psychiatric problem surrounding the psychopathic personality is to understand why an intelligent and rational person might persist in antisocial behaviors in the face of risks and actual punishments that would inhibit most similar impulses in a normal individual. Defined generally, antisocial personality can be regarded as a family of disorders,

comprising at least two genera, which are themselves divisible into "species." One genus might be labeled *sociopaths* and would include those persons of broadly normal temperament who pass through the stages of conduct disorder and delinquency into adult antisocial personality because of parental malfeasance. Although our species evolved a capacity for socialization—for acquiring a self-monitoring conscience, feelings of empathy, altruistic motivations, and a sense of communal responsibility—it appears that, like our capacity for language, this latent talent must be elicited, shaped, and reinforced during childhood. This socialization of children once was the responsibility of the extended family. Judging from the low crime rates that are characteristic of traditional societies still living in extended family groups, most children were successfully socialized in our ancient "environment of evolutionary adaptation." Most modern societies, however, entrust this function only to the child's parents and his peers, and the incidence of sociopathy has risen accordingly. Especially at risk are children reared by single mothers; about 70% of adjudicated delinquents in the United States were reared without the participation of their biological fathers.

A second genus consists of persons whom we might label *psychopaths* and would include species of organic dysfunction or abnormality. Some pathologically impulsive individuals seem to have a specific defect of inhibitory control. Some hyperactive children mature into impulsive psychopaths. Other persons have tyrannical sexual hungers or explosive, uncontrollable tempers or an apparent short-circuiting of aggressive and sexual instincts. These affective disturbances appear to be constitutional in origin and would obviously predispose affected individuals toward antisocial behavior.

The Primary Psychopath

A thoughtful and influential essay on the clinical characteristics of the psychopathic personality, *The Mask of Sanity,* was published in 1941 by psychiatrist Hervey Cleckley. Cleckley's psychopath, "while not deeply vicious, carries disaster lightly in each hand." He may be intelligent and often displays great charm, enhanced undoubtedly by his lack of nervousness or other neurotic manifestations. Yet he is fundamentally unreliable, has a remarkable disregard for truth, and seems incapable of real love or emotional attachment. His antisocial behavior often appears to be inadequately motivated. He takes needless risks, giving the appearance of poor judgment, and shows an indifference to punishment by failing to learn from unpleasant experience. He lacks genuine remorse or shame, often rationalizing his behavior or placing the blame on others. He has a "specific loss of insight," that is, an inability to appreciate how others feel about him or to anticipate how they will react to his outrageous conduct. Notably, in perhaps three cases out of four, "he" is likely to be male.

Cleckley was persuaded that this syndrome results from some deep and probably constitutional defect involving an inability to experience the normal affective accompaniments of experience. Alternatively, it has been suggested that this type of psychopath is distinguished by nothing more exotic than a low "fear IQ." All mammals can experience fear and can learn to associate anxiety with impulses that have been punished or with other stimuli that signal danger. Some people develop conditioned fear responses much more readily than other people do and have high "fear IQs." A child at the low end of this same continuum will be difficult to socialize by the usual techniques of discipline that depend so heavily upon the use of fear and punishment. He may frustrate and antagonize his parents so as to be deprived of the important experience of that prototypic love. It is possible that the average child learns to identify with others as part of a self-protective effort to predict their behavior. Being relatively unconcerned with what others might do or think, the relatively fearless child may invest less effort in this aspect of social learning. One who does not readily identify with others may not readily empathize with others, nor introject their values as required for the normal development of conscience and the capacity for guilt. Fear, and its allies shame, guilt, and embarrassment, seem to be largely responsible for preventing most of us from occasionally committing some of the same misdemeanors that constitute the antisocialism of the psychopath. And the absence of fear, the happy-go-lucky insouciance that emerges when shyness, self-consciousness, guilt, and apprehension are dispelled, is a cardinal attribute of "charm." An important and paradoxical corollary of the "fear IQ" hypothesis is that the child at risk for psychopathy should not be considered sick or defective. His is the stock from which heroes are made. With the right sort of parenting—cultivating a sense of pride and self-respect to substitute for the weak inhibitions of fear and guilt—these children may grow up to be explorers and adventurers, test pilots and astronauts of the kind Tom Wolfe admired in his book *The Right Stuff.*

D. T. Lykken showed in 1957 that the primary psychopath is slow to condition fear to warning signals, tends to ignore painful electric shock in a situation where normals learn to avoid the shock, and seems generally to be less influenced than the average person by reactions of fear or embarrassment. These findings have been replicated and extended by other investigators, most notably by Robert Hare in a series of studies spanning 30 years. Hare has shown, for example, that the primary psychopath displays abnormally little electrodermal arousal in anticipation of a painful shock or a loud blast of noise. Using a startle/stimulus paradigm, C. J. Patrick has shown that frightening or aversive scenes, which enhance startle responses in normal subjects, affect primary psychopaths as do attractive or interesting scenes, by reducing startle.

A genetically determined "low fear IQ," interacting with environmental influences (the style and consistency of par-

enting, etc.), could promote a tendency toward psychopathy. On the other hand, the vast majority of biological relatives of primary psychopaths are not psychopaths themselves.

University of Minnesota

PSYCHOPHYSICS

Psychophysics is the quantitative study of the relation between stimulus and sensation or sensory response. As such, it is concerned with the following questions: (1) How much stimulation is required to produce a sensation or sensory response? (2) How much must a stimulus be changed for the change to be detected? (3) In what way or ways must a stimulus be changed to be perceptually equivalent to another? and (4) How does the sensation or sensory response change with changes in stimulus magnitudes? Answers to these questions, among others, are provided by psychophysical methods. These consist of the three classical methods (limits, adjustment, and constant stimuli) advanced, but not originated, by Gustav T. Fechner (1801–1887) for use in determining thresholds, numerous suprathreshold psychophysical scaling methods used for deriving measures of sensation magnitude, and signal detection theory methods used in providing measures of basic sensory sensitivity, minimally contaminated by motivational and attitudinal biases. Although employed primarily with human subjects, several of the psychophysical methods have been adapted for studying nonhuman sensitivity.

Classical Psychophysics

"By psychophysics," wrote Gustav T. Fechner in his *Elements of Psychophysics* (1966/1860), "I mean a theory which, although ancient as a problem, is new here insofar as its formulation and treatment are concerned; in short, it is an exact theory of the relation of body and mind." Specifically, Fechner attempted to devise a precise and quantitative way of measuring the mind by providing a measure of sensation magnitude.

The idea that strong stimuli generate strong sensations and weak stimuli generate weak sensations was not new. The task was to determine how strong the corresponding sensation was for a given stimulus. Quantitative attempts to do this date back, at least, to the time of the Greek astronomer Hipparchus (160–120 B.C.), who invented the stellar magnitude scale categorizing visible stars into six categories from faintest (sixth magnitude) to brightest (first magnitude). This scale was subsequently found to be approximated by a logarithmic function and consequently was redefined as a logarithmic scale by the British astronomer N. R. Pogson (1829–1891). The concept of a faintest visible star suggests there may be even fainter and invisible stars. Correspondingly, other stimulus dimensions could be divided into perceptible and imperceptible parts. The concept of such a division was incorporated into psychology by Johann Friedrich Herbart (1776–1841) as the threshold (or doorway) into consciousness. The idea of a threshold was influential in Fechner's analysis.

But once into consciousness, how intense is the resulting sensation? This is the basic question of psychophysics. Fechner proposed one answer: $R = k \log (I/I_o)$. The sensation magnitude (R) in Fechner's law varies directly with the logarithm of the stimulus intensity-to-threshold (I/I_o) ratio. An alternative formulation was proposed by the physicist J. A. F. Plateau (1801–1883), who arrived at a power function to describe the sensation of brightness. This formulation has been advanced for other senses as well as vision by S. S. Stevens (1906–1973) in a large number of experiments and theoretical articles (summarized in his *Psychophysics: Introduction to its Perceptual, Neural, and Social Prospects* (1975). The general equation for Stevens' power function is $R = CI^n$, where the sensation magnitude (R) varies directly with the stimulus magnitude (I) raised to a power (n). The value of n depends upon which sense is being stimulated but is considered to be relatively constant over time and across (normal) observers. The constant (C) in the equation is determined by the measurement units used.

These two theoretical formulations—Fechner's law and Stevens' law—describe differently the way sensation magnitude changes with stimulus intensity. Although both state that R increases monotonically with stimulus intensity, different predictions are made about the amount of the increase. Much experimental work has been done using numerous psychophysical methods in an attempt to determine which fits the data better. For example, by using the method of magnitude estimation (which has the observer assign numbers proportional to the stimulus magnitudes), results consistent with Fechner's law would appear as a line when graphed in semilogarithmic coordinates, while those consistent with Stevens' law would be a line in log–log coordinates. Findings have largely supported Stevens' law over Fechner's law, particularly for power functions for which the exponent is 1.0 or larger (e.g., length, duration, electric shock), and for which the predicted results clearly diverge. In those cases for which the exponent is small (e.g., brightness of an extended source or loudness of a sound), data variability may mask the smaller difference in predictions made by the two laws.

Signal Detection Theory

Motivation, expectation, and attitude are biases possessed by the observer in psychophysical threshold determinations. On trials in which no stimulus is presented ("catch trials"), "yes" responses occur (indicating perception of a

nonexistent stimulus). This circumstance in signal detection theory (SDT) is called a false alarm. Correct detection of the stimulus (responding with "yes" when the stimulus is present) is termed a hit. Changes in motivation, expectation, or attitude can increase the hit rate, but at the expense of elevating the false alarm rate. Classical psychophysics attempted to keep the false alarm rate low so that false alarms could safely be ignored in threshold determinations. Signal detection theory gives equal consideration to both hit and false alarm rates in determining an alternative index of sensitivity, which is designated d'. The details for computing d' depend upon the SDT procedure used, and alternative sensitivity indices are used (e.g., percent correct).

The motivational, expectancy, and attitudinal biases are collectively treated as the observer's criterion, which is estimated from the false alarm rate. The criterion can be manipulated by changing the proportion of signal trials (and so informing the observer), by instructing the observer to be more lenient or strict, or by changing the payoffs for different decisions. When data are plotted with hit rate along the ordinate and false alarm rate along the abscissa, different levels for the observer's criterion yield different data points along what is called a receiver operating characteristic (ROC) curve. Different ROC curves are generated by different signal levels, but all points on the same ROC curve represent the same level of detectability. Thus sensory and nonsensory factors can be separately identified.

Applications

Psychophysical theory and methods have found application not only in the analysis of basic sensitivity to stimuli but also in screening for sensory deficits (where an individual's threshold is compared with known normal values), in the design of equipment and signaling devices in engineering psychology, in the study of memory using signal detection techniques, and in the comparative evaluation of clinical diagnostic tests.

PSYCHOPHYSICS AND COMPUTATIONAL MODELING OF MOTION PERCEPTION

We live, we walk or drive, we turn our head or shift our gaze in a world full of living or humanly created objects that move themselves. In consequence, the image on our retina is never still, and visual motion processing is a distributed and continuous activity of nervous systems, of which we only become aware when we have to solve specific problems, such as catching a ball or assessing the approach of a vehicle. So it is not surprising that motion perception has a long tradition as a research topic (Wade, 1998), starting from classical observations of the waterfall illusion: After prolonged exposure to visual motion, for instance when watching a stream of water, static objects are perceived as moving in the opposite direction—also referred to as motion after-effect. A typical aspect of traditional psychophysics is the attempt to trick the visual system by creating motion sensations from still images, which led to practical applications like "movies." The study of motion-perception-like phenomena in animal systems, from insects to primates, has provided valuable clues to the neural basis of motion processing, and suggested computational models that are increasingly relevant for machine vision. Thus, motion vision can be regarded as an exemplar for the understanding of perception in terms of its underlying brain mechanisms.

Basic Processing Steps

Experiments carried out by Exner in the late nineteenth century mark a fundamental step towards the functional understanding of motion perception. Electric sparks elicited the sensation of apparent motion when presented in rapid succession as alternating between two locations

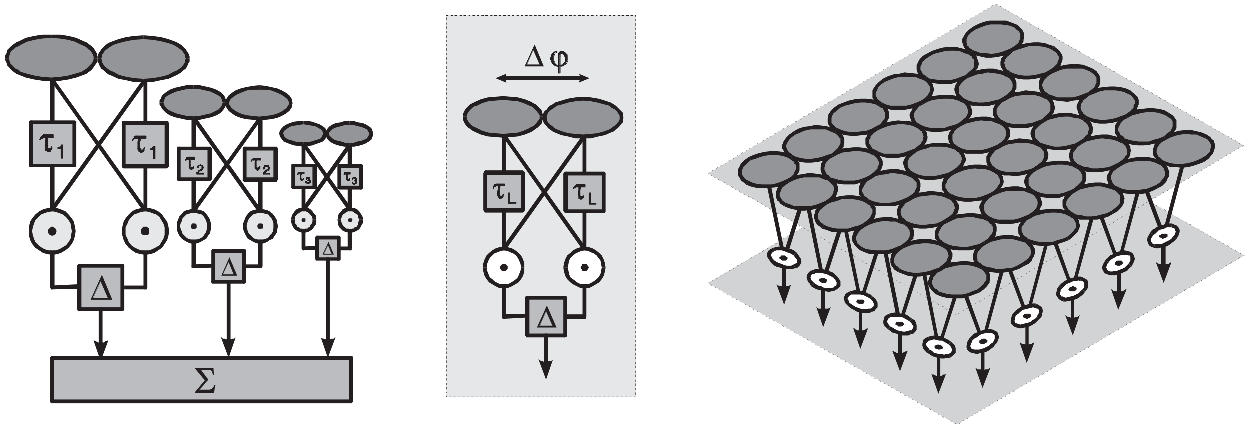

Figure 1. Models of motion perception: elementary motion detector (EMD, middle), two-dimensional arrays (right), spatiotemporal pooling (left).

that could not be resolved with synchronous presentation. This experiment not only demonstrates motion as an independent perceptual entity, but also suggests the basic components of a mechanism to detect visual motion by defining the crucial components of a minimum motion stimulus. For half a century, real and apparent motion stimuli were studied mainly in the framework of a Gestalt psychology seeking to define the crucial attributes that constitute a particular motion percept, before low-level mechanisms returned to the center of attention in the second half of the twentieth century. An elementary motion detector model (EMD), which was originally derived from the analysis of insect vision, turned out to be rather successful in describing the function of a variety of visual systems. The EMD (Figure 1, center) consists of four fundamental operations: (1) two input elements, separated by the sampling base $\Delta\varphi$, pick up luminance signals from neighboring locations in the visual scene; (2) temporal filters delay the input signals with a time constant τ; (3) the original signal from one location interacts with the filtered signal from the other location (multiplication); and (4) the outputs of two mirror-symmetric subunits are subtracted (opponency, indicated by Δ). Whereas the magnitude of the final EMD output does depend on the speed, contrast, and spatial properties of the stimulus, the direction of motion is clearly reflected by the sign of the output (Borst & Egelhaaf, 1989). Thus motion is detected with a small number of simple operations, all of which can be easily realized with neural processing elements.

Local Motion Detection

A number of perceptual features can be expected from this EMD model that represent a class of "correlation" or "motion energy" models. The specific spatial and temporal tuning of the EMD, related to $\Delta\varphi$ and τ, is often used as the fingerprint of this mechanism, eliciting a maximum response for moving gratings at a constant rate of light change (a "temporal frequency optimum"). This and other predictions from the EMD model are consistent with behavioral and physiological evidence from a wide range of animal species. In particular, motion detection and direction discrimination, as well as motion after-effects, depend on temporal frequency, suggesting that EMD design principles are implemented in human vision. Another, even more obvious prediction derived from the EMD model is the existence of displacement limits for motion detection—that is, pattern displacement will no longer be detected once it moves beyond the sampling base of the EMD. This is exactly what was found in a number of experiments where stimuli were generated from randomly distributed dots, which do not allow the identification of objects without motion being detected in the first place. Based on the displacement limits for such Random Dot Kinematograms, a "short-range" process that relies on spatiotemporal correlation, is distinguished from a "long-range" process that identifies and tracks features or objects during a motion sequence (Braddick, 1980).

Motion Integration

The basic motion detection mechanism, and the EMD model, is just the starting point for a cascade of processing steps in which such local filters are combined in various ways.

- Spatial or temporal pooling helps to reduce noise that is inherent to neural processing and is ambient in natural scenes.
- Two-dimensional arrays of motion detectors (Figure 1, right) are required to analyze distributions of motion signals, such as the characteristic "flowfields" generated by movements of the observer (Gibson, 1979) or the boundaries between regions which are characterized by different velocities (to detect camouflaged objects).
- For speed estimation it is necessary to integrate the outputs from EMD units that are tuned to different

spatiotemporal frequencies (by variation of $\Delta\varphi$ and τ, see Figure 1, left). This operation is important for a number of motor control tasks, and can also lead to the reduction of noise (Zanker & Braddick, 1999).

- Motion detectors may operate on a variety of inputs, such as luminance, color, texture, or motion itself. Additional nonlinear processing steps give rise to "first-" and "second-order" motion detection, finally leading to a parallel and hierarchical processing system which is able to extract a wide variety of motion cues (Cavanagh & Mather, 1989).

The complexity indicated by this brief overview of possible interactions between local motion detectors reflects the scope and the significance of motion vision tasks confronting the visual system with an immense flow of visual information, which need to be solved effortlessly when navigating safely through everyday life.

PSYCHOPHYSIOLOGY

Psychophysiology is the study of mental or emotional processes as revealed through involuntary physiological reactions that can be monitored in an intact subject. In psychophysiological research the independent variables will usually be psychological, while the dependent variables will be physiological changes that can be recorded peripherally either as electrical signals (e.g., brain waves, muscle potentials, the electrocardiogram) or as pressure, volume, or temperature changes (e.g., breathing movements, blood pressure, skin temperature).

Psychophysiological Measurement

The immediate object of psychophysiological measurement is to generate an electrical signal that faithfully mimics the manner in which the physiological phenomenon being measured varies over time. Once the phenomenon has been represented as an electrical signal, it can easily be amplified or filtered, visualized as a tracing on a computer screen, and stored for later playback and analysis. Some psychophysiological phenomena, such as the electroencephalogram (EEG), the electromyogram (EMG), and the electrocardiogram (ECG), are already electrical signals generated in the body and their measurement requires only a pair of electrodes, appropriately placed to pick up the biological voltage and connected to the input of an amplifier that will boost this voltage until it is strong enough to be recorded in some way. Electrodes used in psychophysiology are junctions where the flow of electric current changes from electronic, in the wires of the external circuitry, to ionic, in the skin and other tissues. Such an interface is subject to electrochemical processes that can produce polarization. A polarized electrode acts like a high-pass filter that discriminates against slow or low-frequency changes. Relatively nonpolarizing electrodes are available, typically made of silver coated with silver chloride. An electrode paste or electrolyte is applied between the skin surface and the electrode; the properties of this conductive paste are also important for successful recording.

Phenomena such as pressure or temperature changes can be converted into electrical signals by means of an appropriate transducer. For example, a thermister is a device whose electrical resistance varies reliably with temperature; by passing a weak electric current through a thermister probe and amplifying the voltage developed across it, one can produce a signal that accurately represents changes in temperature. A strain gauge, similarly, changes in resistance as it is flexed and can therefore act as the "sense organ" of a pressure transducer or of a device for measuring, for example, breathing movements.

Some psychophysiological phenomena that do not produce signal voltages directly may involve changes in the electrical properties of tissue that can be measured by passing an external sensing current through the tissue; the electrical conductance of the palmar skin is one example. The standard technique for measuring the skin conductance response (SCR) involves applying a constant voltage of 0.5 volt between two nonpolarizing electrodes attached to the palmar skin surface and measuring the small direct-current flow (less than 10 microamperes per square centimeter) through the tissues.

Noise

The modern world is literally full of electrical "noise," electromagnetic emanations from television transmitters, electric motors, passing autos, fluorescent lights, and so forth,

which the human body picks up as an antenna does. Bioelectric signals originating in the body, similarly, become noise when they are not the signal one wants to measure but appear nonetheless in one's recordings. Noise of biological origin, as when eye movements affect the EEG or when the ECG shows up unwanted in the electrodermal channel, requires special solutions. Sometimes reorientation of the electrodes will suffice. If the noise consists mainly of frequencies outside the bandwidth of the desired signal, a bandpass filter may provide the solution. A third approach is to measure the noise directly in a separate channel and then subtract it from the signal channel by electronic inversion and summation.

Analyzing the Data

The variance of a sample of scores on some psychophysiological variable can be partitioned thus:

$$\sigma^2_\omega = \sigma^2_\psi + \sigma^2_\phi + \sigma^2_\varepsilon \qquad (1)$$

where σ^2_ψ is the variance due to individual differences in the underlying psychological variable of interest, σ^2_ϕ is the orthogonal component of variance due to physiological differences, and σ^2_ε represents measurement error. If skin conductance level (SCL), represented by ω, is being measured, for example, ψ might be central nervous system (CNS) arousal or "energy mobilization," ϕ would reflect individual differences in the density and activity of volar sweat glands, and ε would increase with variations in cleaning the skin surface, in positioning of the electrodes, in the area of skin contacting the electrolyte, and so on.

Underlying most psychophysiological measurement is the implicit assumption that ω is a monotonically increasing function—and, it is hoped, a simple linear function—of the underlying variable of interest, ψ, as in:

$$\omega = a + b\psi + \varepsilon. \qquad (2)$$

Using SCL again as the example, the parameter *a* would represent this subject's minimum SCL when sudomotor activity is zero, while *b* would be determined by the reactivity of the entire electrodermal system, that is, the increase in conductivity produced by a unit increase in ψ. (Very similar assumptions are implicit in most psychological measurement.) The problem is that the parameters *a* and *b* also vary, often within the same individual from time to time, and certainly from one individual to another. This is the variation represented by σ^2_ϕ, in equation 1. The job of the psychophysiologist is, first, to ensure that the physiological variable chosen (ω) *is* linearly related to ψ, at least approximately, and then to try to minimize both measurement error σ^2_ε, and also σ^2_ϕ, the variance due to physiological variability, within subjects or between subjects, which also must be regarded as error variance in this context.

PSYCHOSEXUAL STAGES

In Sigmund Freud's (1938) personality theory, development is described in terms of stages defined by the specific expression of sexual, or libidinal, urges. Those areas of the body—the erogenous zones—that give rise to libidinal pleasure at specific ages are identified as the focus of each developmental stage. Thus the pleasure derived from sucking liquids and mouthing foods is the focus of the first developmental period, the *oral stage.* The satisfaction surrounding the retaining and expelling of feces defines the second, *anal stage.* The *phallic stage* refers to the period in which the young child begins to explore and derive pleasure from the genitals. These three stages, called the pregenital stages, span, respectively, the first year of life, the second two years, and the years from three to five, roughly.

The pregenital stages are followed by a period of supposed psychosexual quiescence, the *latency period,* which lasts until the onset of puberty. Puberty, however, brings with it a resurgence of the pregenital urges, which now focus specifically on the pleasures deriving from the genital organs; thus the name of this final developmental period, the *genital stage.*

Libidinal urges in Freudian theory are not equatable with genital sexuality. For example, three of the psychosexual stages are "pregenital." The term *libido* is meant to define a broad concept of mental sexual energy occurring even in infancy. Nor do the stages refer only to male sexuality, despite the masculine language. For example, the phallic stage refers to the last pregenital stage of both sexes.

Oral Stage

The oral stage of development is characterized by a need for nurturance and by pleasure derived primarily from activities of the mouth and lips, such as sucking, mouthing, and swallowing of food, as well as, later, the biting and chewing

of food. These early gratifications are said to be the precursors of the development of later character traits. Thus, the two main sources of oral pleasure, oral incorporation and biting (seen as aggressive), may be the prototypes for later habits and personality traits. Oral incorporation as a predominant trait may lead to the acquisition of material things and acquisitiveness in personal relationships. An oral aggressive style may include such behavior traits as "biting" sarcasm, "chewing out" an opponent, and spewing out an invective. Dependency and need for approval are seen as main components of the oral character. Some evidence for this relationship has been found by Joseph Masling et al. (1968), who found that conforming college students gave a significantly greater number of "oral-dependent" responses on the Rorschach test, when compared with less conforming subjects.

Anal Stage

The anal stage extends approximately from one year of age to two, when bowel and bladder control is a primary task, and the pleasure and pain derived from expelling and retaining feces are the main libidinal outlet. The toddler in the anal period is growing in independence and self-assertion. Freud saw the events surrounding the task of toilet training as crucial for later character formation. A child who is harshly trained and severely punished for accidents before acquiring control may express rage by defecating at will at inappropriate times or by being selfish and stingy (anal retentive). Conversely, the child who is rewarded and praised for control efforts becomes the generous (anal expulsive) and often creative individual. Overindulgence can lead to messiness and vagueness (Maddi, 1972, p. 273).

Phallic Stage

Between 2 and 3 years of age, the child begins more active body exploration. The locus of erotic pleasure shifts from the anus to the genitals as the young child discovers the pleasurable effects of masturbation. One of the main tenets of Freudian theory, the Oedipus complex, has its origins in this stage. Named for the mythical Greek king of Thebes who killed his father and married his mother, the Oedipus complex refers to the child's incestuous desire for the opposite-sexed parent. In the boy, the simultaneous pleasure from autoerotic activity coupled with a desire for the mother and a rivalry with his father generates anger in his father, which the boy perceives as a threat. Since the erotic pleasure emanates from the genitals, the boy assumes that the father may destroy them. Freud called this perceived threat *castration anxiety.*

The resolution of the Oedipus complex in the girl is not as clear in Freudian theory. Since castration to the girl appears to be a *fait accompli,* she blames her mother, whom she sees as sharing her plight, and envies the male for his organ and favored position and power. Freud's term for this condition was *penis envy.* The girl gradually gives up her attachment to her father and begins to identify with her mother.

Genital Stage

After a period of psychosexual quiescence, termed latency, puberty brings with it a resurgence of the phallic strivings and more realistic capabilities for their expression. Once again, masturbation becomes a source of erotic satisfaction, and appears so nearly universal and urgent that Freud called this adolescent impulse *onanism of necessity.* Armed with full adult genitalia and sexual drives, the growing adolescent shifts his or her affection from parents to peers, first of the same sex (a brief homosexual phase, just after puberty), and then of the opposite sex. In the fully integrated adult, the psychosexual urges most often find expression in activity with an opposite-sexed partner of roughly the same age. More important, these urges no longer are purely narcissistic, as they were in the pregenital stages. The psychosexual urges now extend and generalize to altruism, friendship, sharing, and loving of a more adult nature.

PSYCHOSOMATIC DISORDERS

The term *psychosomatic disorder* generally refers to a type of physical condition in which the etiology or course is related to significant psychological factors. A psychosomatic disorder involves a demonstrable organic pathology, such as a duodenal ulcer, or a known pathophysiological process, such as a migraine headache. These conditions usually include such disorders as rheumatoid arthritis, asthma, and essential hypertension, and are not limited to a single physiological system.

Psychosomatic disorders, also known as psychophysiologic disorders, were not specifically listed in the fourth edi-

tion of the *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition (*DSM-IV*), but are referred to as "psychological factors affecting medical condition," and in the ninth edition of the *International Classification of Diseases* (*ICD-9*) as "psychic factors associated with diseases classified elsewhere."

Historical Background

Psychosomatic concepts have roots in ancient philosophical thoughts about mind-body relationships. Emperor Huang Ti (c. 2697–2597 B.C.) recorded in his *Classic of Internal Medicine* keen observations on the etiology, diagnosis, treatment, and prognosis of psychosomatic illnesses. Herbal doctors of the Babylonian-Assyrian civilization (c. 2500–500 B.C.) considered sin to be the source of sickness and exorcism to be the cure, with mind and body interaction being central to their concept of disease.

Socrates (496–399 B.C.) and Hippocrates (466–375 B.C.) also offered early acknowledgment of the role of mental factors in health and disease. Heinroth in 1818 first employed the word "psychosomatic," a term later popularized by German psychiatrist Jacobi. Scientific medicine achieved major progress toward the end of the nineteenth century, with an emphasis on physical disease, as a result of the discoveries in morbid anatomy, microbiology, and biochemistry. The gap between the biological and the psychological aspects of illness remained until a rapprochement began to develop in the early twentieth century, largely because of the work of Freud, Pavlov, and Cannon. Freud's elaboration of the unconscious, Pavlov's studies of the conditioned reflex, and Cannon's notion of fight and flight reactions offered important psychological concepts that stimulated the growth of the psychosomatic approach in health care.

A psychosomatic movement began in Germany and Austria in the 1920s, and many Europeans, such as Alexander, migrated to the United States, bringing along the European interest in psychosomatic disorders. In 1939, the birth of the journal *Psychosomatic Medicine,* under the editorship of Dunbar, reflected the growing interest in this field in the United States. Important volumes began to appear in the 1940s and 1950s, including Weiss and English's *Psychosomatic Medicine,* Alexander's *Psychosomatic Medicine,* and Grinker's *Psychosomatic Research.*

Early psychosomatic methodology consisted mainly of clinical observations. By the late 1950s, an increasing number of psychologists were engaged in laboratory and clinical psychosomatic experiments. There was a declining interest in researching psychoanalytic concepts in psychosomatic problems, accompanied by a growing trend toward experimental research studying human biological response to hypnotic techniques, conditioning, and sensory input and deprivation. Psychosomatic research with animals provided a large body of scientific information, with relevant implications for human physiology and clinical practice.

Theoretical Concepts

Although Freud never mentioned "psychosomatic disorder" in his writings, he stressed the role of psychic determinism in somatic conversion hysteria. Freud's followers provided further refinement of psychoanalytic concepts vis-à-vis psychosomatic phenomena, including Dunbar's description of personality profiles (e.g., the ulcer personality, the coronary personality, and the arthritic personality), as well as Alexander's analysis of psychodynamic patterns underlying asthma, ulcers, arthritis, hypertension, and other disorders.

Important psychosomatic concepts also emerged in nonpsychoanalytic schools. Corticovisceral theory prevailed in Eastern Europe, dominated by Pavlovian neurophysiology and conditioning research. In the United States, psychological stress theory, such as Cannon's concept of bodily homeostasis, Wolff's research on the adaptive biological responses, and Selye's work on pituitary adrenal responses formed the foundation for psychosomatic research and clinical approaches. Social or ecological concepts have also been elaborated, as in the early Midtown Manhattan Project or the more recent life-change studies by Rahe and Holmes.

Type of Disease

In 1950, Alexander listed seven classic psychosomatic diseases: essential hypertension, peptic ulcer, rheumatoid arthritis, hyperthyroidism, bronchial asthma, colitis, and neurodermatitis. More recently, the extensive classification system of the ninth *International Classification of Diseases* provided a comprehensive list of psychosomatic disorders, including the following:

1. Psychosomatic disorders involving tissue damage, such as asthma, dermatitis, eczema, gastric ulcer, mucous colitis, ulcerative colitis, urticaria, and psychosocial dwarfism.
2. Psychosomatic disorders not involving tissue damage, such as psychogenic torticollis, air hunger, psychogenic hiccup, hyperventilation, psychogenic cough, yawning, cardiac neurosis, cardiovascular neurosis, neurocirculatory asthenia, psychogenic cardiovascular disorder, psychogenic pruritus, aerophagy, psychogenic cyclical vomiting, psychogenic dysmenorrhea, and teeth grinding. A psychosomatic syndrome can also be categorized according to the major organ systems affected.

In the following, psychological factors may be a cause or an aggravating stress that affects the course of the disorder.

1. Gastrointestinal disorders: gastric and duodenal ulcers, ulcerative colitis, anorexia nervosa, bulimia, obesity, irritable colon, spastic colitis.

2. Respiratory disorders: asthma, hyperventilation, tuberculosis.
3. Skin disorders: neurodermatitis or eczema, pruritus, urticaria, psoriasis, skin allergies, herpes.
4. Musculoskeletal disorders: rheumatoid arthritis, temporomandibular jaw syndrome, muscle contraction headache.
5. Metabolic and endocrine disorders: thyrotoxicosis, myxedema, diabetes mellitus, Addison's disease, Cushing's syndrome, parathyroid disease, hypoglycemia.
6. Gynecological and obstetrical disorders: menstrual disorders (premenstrual tension, menorrhagia, pseudocyesis), conception and pregnancy (sterility, spontaneous abortion).
7. Cardiovascular disorders: coronary artery disease, essential hypertension, congestive heart failure, vasodepressive syncope, migraine headaches, angina pectoris, arrhythmia, cardiospasm, tachycardia.
8. Hematological disorders: hemophilia.
9. Others: immune diseases, chronic pain syndrome, allergic reactions.

Treatment

The early roots of psychosomatic medicine consisted of psychoanalytically oriented therapies, such as those of Alexander and his associates. In more recent decades, nonanalytic psychotherapies have become more prominent. With the increasing sophistication in pharmacotherapies, psychiatrists find the use of psychotropic medications helpful, including various tranquilizers and antidepressants. Group psychotherapy is especially suitable for certain psychosomatic patients, such as those with bronchial asthma, who find relief in meeting others with similar concerns and learn to identify and verbalize significant feelings related to this condition.

In cases where psychosomatic reactions may be the result of learned patterns of behavior—for example, certain sexual dysfunctions—behavior therapy is an effective therapeutic method. Behavioral approaches have been demonstrated to be effective components of interventions for hypertension, arthritis, pain, obesity, and bulimia nervosa.

Recent decades have seen a rapid growth in psychologists' employment of behavior modification techniques, exercise, and relaxation therapies, such as Jacobson's progressive relaxation, Luthe's autogenic training, and biofeedback to treat headaches and other stress-related disorders. In addition, principles and methods of transcendental meditation, yoga, controlled breathing, and Morita therapy have also been used with psychosomatic disorders.

PSYCHOSTIMULANT TREATMENT FOR CHILDREN

The putative efficacy of psychostimulants as a first-line treatment for children with Attention-Deficit/Hyperactivity Disorder (ADHD) is well documented and deserved. Few treatments provide benefit to such a large percentage of individuals affected with a particular disorder and improve functioning in multiple domains. Positive effects are ascertained in an estimated 50% to 96% of children with ADHD, depending on the stringency with which positive response is defined and the particular outcome variable targeted. For example, positive treatment response is estimated to occur in 70% of children undergoing psychostimulant therapy, whereas an overall 96% improvement rate in behavior problems is demonstrated when response is defined as improvement on any one of several alternative psychostimulants. Conversely, others have shown response rates to vary between 53% and 94% for academic efficiency and teacher-rated classroom behavior, respectively, when positive response is evaluated using psychometric indices such as statistically derived normative comparison scores (Rapport, Denney, DuPaul, & Gardner, 1994).

The breadth of domains shown to improve with psychostimulant treatment is equally impressive. These include direct observations of children's attention, behavior, and academic performance (Rapport et al., 1994), parent/teacher ratings of social deportment, performance on a wide range of clinic-based neurocognitive tests, tasks, and paradigms (for a review, see Rapport & Kelly, 1991), peer relationships and interpersonal behavior, and even participation in some extracurricular activities. Titrating MPH (i.e., determining the correct dosage), however, has become increasingly more complex in recent years. Issues related to determining appropriate dosage and which behaviors or variables to target for intervention are discussed below.

Titrating Psychostimulants

Methylphenidate (MPH) is currently the most widely prescribed psychostimulant for treating children with ADHD,

albeit several alternative formulations such as Concerta, Metadate, and Adderall are now available and their effects on behavior last substantially longer than those obtained from a standard tablet of MPH. Adderall is the best studied of the alternatives. It appears to be therapeutically equivalent to standard MPH in affecting behavior; however, limited information is available concerning its effects on cognitive function in children.

Several misconceptions concerning both the initial titration of and dosage effects associated with psychostimulants prevail. Popular among these is the notion that a child's gross body weight should be used to establish initial dosage parameters, using a milligram of medicine per kilogram of body weight (mg/kg) ratio—the implicit assumption being that heavier children require more medicine than do lighter-weight children. Two studies have addressed this issue in recent years, with both reporting a lack of relationship (not even a trend) between children's body weight and clinical response to methylphenidate (MPH).

A more complicated issue concerns the dose-response nature of psychostimulants. For example, there is widespread belief that different behavioral domains are optimized at widely discrepant dosage levels in children. Many clinicians believe that lower dosages optimize cognitive performance whereas higher dosages are needed to optimize behavior and manageability in the classroom. Neither comprehensive literature reviews (see Rapport & Kelly, 1991) nor direct observations of children receiving psychostimulant treatment while working in classroom or laboratory environments have supported this contention. Instead, both classroom behavior and cognitive performance (including academic performance) have been found to be affected at similar dosage levels, usually within the middle to higher dosage range when using MPH (Rapport et al., 1994). It should be stressed, however, that these results are based on average responses of large groups of children. The optimal dosage for a particular child must be carefully determined in the context of a controlled medication trial.

Selecting Appropriate Target Behaviors

Most children are prescribed psychostimulants by their primary physician and seen routinely in an office setting for purposes of monitoring treatment effectiveness (including the possibility of emergent symptoms or side effects). Physicians, in turn, rely primarily on parent and teacher reports to (1) establish whether a child has shown a favorable response to the medication, and (2) determine the most effective dosage. What would appear to be a relatively straightforward endeavor is in fact complicated by a number of factors. Neither children nor their parents are particularly astute at delineating positive treatment effects. Because of the relatively short behavioral life of MPH (approximately 4 to 5 hours from time of ingestion) and dissimilarities between the home and classroom setting (particularly the fewer cognitive demands associated with the former), parents are not ideally situated to judge treatment effectiveness. Moreover, the findings of a recent study reveal that neither initial presenting characteristics of the child (e.g., level of pretreatment hyperactivity, age) nor changes in particular behavioral domains (e.g., attention, reduced impulsivity) portend improvement in other important areas such as academic functioning (Denney & Rapport, 1999). Conversely, improved academic functioning nearly always coincides with improved behavior. The essence of this finding is that children's academic performance in the classroom should serve as the primary target for titrating psychostimulants in children. Assessment of this domain can be accomplished by using the Academic Performance Rating Scale (APRS; DuPaul, Rapport, & Perriello, 1991) or a similar instrument that provides a valid index of children's classroom academic performance.

Conclusions

The use of psychostimulants as a therapeutic regimen to treat children with ADHD remains a controversial topic. A majority of children derive clear and sustained benefit from this therapeutic modality, although most experienced clinicians and researchers concur that neither this nor any treatment regimen used alone adequately addresses the multifaceted difficulties associated with ADHD. When used, a controlled medication trial incorporating a wide range of dosages is recommended owing to the unique response children exhibit to psychostimulants. Outcome assessment should, at the very least, include multiple, standardized, treatment-sensitive measures across settings (home and school) throughout the duration of the clinical trial as well as at scheduled intervals thereafter to assess continuity and maintenance of treatment effects. Finally, clinical indices of improvement should ideally include measures from both the behavioral and cognitive (academic) domains, owing to the latter variable's established relationship with long-term academic achievement and adult outcome.

PSYCHOSURGERY

Psychosurgery, by definition, implies the destruction of brain tissue for the relief of severe, persistent, and debilitating psychiatric symptomatology. Its use can be traced back with early archeological evidence of trepanation in 2000 B.C. (Valenstein, 1980). However, the first widespread application of psychosurgical procedures to psychiatric patients began in the late 1930s, reached its peak in the 1960s, and began to decline in the 1970s (Weingarten & Cummings, 2001).

In the first half of this century, the technique most frequently used for creating lesions was frontal lobotomy, wherein fibers in the frontal lobes were cut bilaterally. Initially this was accomplished by placing a cutting instrument through a cannula into burr holes drilled through the skull, or by placing it through the bony orbits above the eyes, and then rotating the instrument. More precise placement of lesions became possible during the 1950s as a result of the invention of a stereotaxic instrument that held the head in a fixed position. A knife or electrode could then be lowered into the brain at a point predetermined by a set of three-dimensional coordinates as defined by a brain map or atlas. In this manner, well-localized lesions could be made. This treatment was initially used largely for the treatment of Schizophrenia. The use of knife cuts was gradually replaced by the use of electric currents or radiofrequency waves delivered through electrodes. Some neurosurgeons have also used cryoprobes, radioisotopes, proton beams, ultrasound, and thermocoagulation for this purpose (Weingarten & Cummings, 2001).

Emotional changes occur in a variety of neurological disorders including epilepsy, stroke, and trauma. Clinically, it has been noted that lesions in distinctly different areas of the brain will disrupt emotional processing at different levels or stages. Therefore, a common feature shared by theories of emotional dysfunction is that multiple brain systems are involved (Borod, 2000; Davidson, Pizzagalli, Nitschke, & Putnam, 2002; LeDoux 2000). Some theories accent the role of the right hemisphere in emotion, and other theories emphasize frontal-cortical-subcortical system connections. Still others have advanced modular models that combine concepts from lateral dominance with ideas about the brain's other axes (dorsal-ventral and anterior-posterior). Here, the right hemisphere's putative role in emotion is modified by a valence hypothesis: The right hemisphere controls negative emotions, while the left controls positive emotions. In more recent years, psychosurgery has been used in the treatment of refractory obsessive-compulsive disorder and in refractory depression.

In the main, psychosurgery has targeted bilateral brain systems. The most effective early targets for relief of psychiatric symptoms appear to involve the medial and ventral areas of the frontal lobes. Other regions of the brain with well-defined connections to specific frontal areas have been selected as targets for psychosurgery. These connecting regions include the cingulum, the amygdala, several areas in the thalamus and hypothalamus, and anterior portions of the internal capsule (to interrupt frontothalamic projections). The term *tractotomy* refers to the interruption of fiber tracts connecting frontal areas with lower brain centers, and it has been used in the treatment of severe depression, anxiety, and Obsessive-Compulsive Disorder. Amygdalotomy has been effective in some patients with aggressive behaviors associated with temporal lobe epilepsy (Jasper, Riggio, & Goldman-Rakic, 1995). Pallidotomy in patients with severe Parkinson's disease restores, in some cases, relatively normal motor function (see Lang & Lozano, 1998). It remains to be seen, however, how long the beneficial effects last.

Since psychosurgery for psychiatric patients has often been performed on apparently normal brain tissue, its practice has generated considerable controversy. The National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research supported several intensive investigations on the use and efficacy of psychosurgery. As indicated in a resultant report by the U.S. Department of Health, Education and Welfare and the follow-up reports published in Valenstein's book (Valenstein, 1980), the Commission considered many pros and cons, including risks and benefits. Opponents of the use of psychosurgery have compared it to the abuses of human subjects in biomedical experiments carried out in Germany during World War II. Those in favor of psychosurgery have argued that its prohibition would rob patients of their right to effective medical treatment by limiting the scope of procedures available.

On the basis of the diverse and extensive information reviewed by the Commission, recommendations were made to the U.S. Department of Health and Human Services (DHHS) regarding the use of psychosurgery. One recommendation encouraged DHHS to support evaluative studies of the safety and efficacy of the procedures, and two other recommendations detailed conditions for, and ap-

proval of, their limited use with institutionalized individuals. Obviously psychosurgery is a topic that involves many ethical, scientific, and legal concerns, and there is no easy resolution of the controversy associated with its use.

PSYCHOTHERAPY

Definition and Utilization

What is psychotherapy? Although originally defined as one-on-one sessions between a patient and therapist with the intent of changing the inner workings of the patient's psychological life, over the last several decades psychotherapy has broadened in its formats, participants, procedures, and focus (there are now over 250 different forms of psychotherapy) so that any definition of psychotherapy must be far-ranging enough to encompass the full spectrum of different "psychotherapies." What relaxation therapy, family therapy, cognitive therapy, group therapy, insight-oriented therapy, play therapy (with children), exposure therapy—to name a few—have in common is a set of psychological or behavioral procedures, delivered by one or more therapists, designed to change the thoughts, feelings, somatic symptoms, or behaviors of one or more participants who are seeking help.

Although the practice of psychotherapy is not regulated, it is generally delivered by psychologists, psychiatrists, social workers, family therapists, psychiatric nurses, pastoral counselors, or addiction counselors. Surveys have found that 2.2% to 4.4% (depending on the city) of the United States population makes at least one visit to a mental health specialist in a 6-month period (Hough, Landsverk, Karno, & Burnam, 1987). People who seek psychotherapy do so for a variety of reasons, including treatment for an ongoing psychiatric disorder such as Agoraphobia or depression, difficulty coping with recent stressful life events, or desire for more success or satisfaction with life.

History

Psychotherapy in its modern form can be traced to Sigmund Freud in the late nineteenth century. Psychoanalysis was developed as a long-term treatment designed to bring to the patient's awareness repressed unconscious conflicts. Despite the large number of brands of psychotherapy today, only a few general schools have continued to be influential. The psychodynamic, or analytic, school continued to develop over the twentieth century. Under the influence of Sandor Ferenczi, Otto Rank, Franz Alexander, and Thomas French, the analytic school shifted towards shorter-term treatments that included increased therapist activity. Modern psychodynamic therapy evolved in the 1970s under the influence of Malan, Mann, Sifneos, and Davanloo, who encouraged a focal treatment that explored patients' maladaptive interpersonal styles within the context of time limits. In the 1980s, Luborsky and Strupp and Binder published manuals for implementing short-term dynamic psychotherapy. These treatments focus mainly on the interpretation of maladaptive relationship patterns as they influence the patient's current relationships and functioning, provided in the context of a supportive therapeutic relationship.

Closely related to dynamic treatments, the interpersonal school was first described by Harry Stack Sullivan. Sullivan focused on interpersonal relationships as they influenced the development of the patient's personality. In 1984, Klerman, Weissman, Rounsaville, and Chevron published a manual for interpersonal psychotherapy. This treatment emphasizes the patient's current interpersonal relationships. Unlike dynamic treatments, developmental factors and maladaptive relationship patterns as they are expressed in the therapeutic relationship are not given direct attention.

Carl Rogers developed the client-centered school of psychotherapy. This approach focuses on the psychological climate created by the therapist. An environment characterized by genuine acceptance, sensitive understanding, and empathic understanding is believed to foster within the patient the ability to reorganize his or her personality. Unlike dynamic therapy, the climate of the therapeutic relationship alone is believed to foster the patient's gains.

The behavioral school of psychotherapy has also remained influential. Behavior therapy has its base in learning theory. The model postulates that symptoms are a result of learned behaviors that are subject to direct manipulation by contingency management and classical conditioning. Techniques focus on modifying behavior through positive and negative reinforcement and desensitization.

The cognitive school of psychotherapy was founded by Albert Ellis in the 1950s. In Rational Emotive Therapy, problems are seen as a result of faulty expectations and irrational thoughts. The goal of this treatment is to teach patients to modify their thinking patterns. In 1979, Aaron Beck published a manual of cognitive therapy for depression. This treatment focuses on identifying, testing the validity of, and correcting the dysfunctional beliefs that underlie the patient's cognitions.

These types of psychotherapy are applied in both an individual and group format. In individual therapy, the therapist works one-on-one with the patient, while group formats may include couples, families, or groups of strangers brought together to work on a specific topic. The family systems approach to psychotherapy focuses on each family member as coequal in importance. The therapist helps the members identify problems in the family system and reorganize themselves as an effective family unit.

A recent trend to emphasize the common factors across the various schools of psychotherapy has paved the way for the movement toward integration of different approaches. Many practitioners find it useful to borrow techniques from multiple schools to maximize patient benefit. Cognitive and behavioral techniques are often used in combination and are seen as important complements to each other in the therapeutic process.

Another recent trend has been toward brief, rather than long-term, treatment. This trend has been influenced in part by research conducted on brief therapy, and in part because of the need to contain health care costs (i.e., most insurance companies will only pay for a limited number of sessions of psychotherapy).

Research on Psychotherapy

Although many are skeptical of psychotherapy as a treatment, it has been investigated in research studies more than any other medical procedure, with well over 1,000 studies of psychotherapy performed to date. Extensive reviews of the research literature have concluded that, broadly speaking, psychotherapy works. Research is now directed toward the more specific question of finding out which type of psychotherapy procedure works best with identified types of patient problems or disorders, and developing new techniques for enhancing treatment benefits. Other research examines psychotherapy as it is delivered in the community—its effectiveness, cost, and dose-response relationships. Still yet another form of psychotherapy research (process studies) looks at what actually happens during psychotherapy sessions and attempts to unravel the relationship between the actions of the therapist in sessions and changes in the patient(s).

Research on specific treatment procedures for different problems and disorders has led to recommendations about which psychotherapy procedures have sufficient empirical support. These recommendations are based largely upon the results of studies in which patients are randomly assigned to psychotherapy versus a control group (e.g., a waiting list or a psychological or pill placebo). Specific psychotherapies have received strong empirical support as treatments for Obsessive-Compulsive Disorder, Major Depressive Disorder, Panic Disorder, Agoraphobia, and Generalized Anxiety Disorder (Chambless et al., 1996). For these disorders, the relative effectiveness of psychotherapy compared to psychotropic medication, or the combination of medication and psychotherapy, is of high public health significance and is a topic of much ongoing research.

Studies of psychotherapy as it is practiced in the community have yielded important data on the number of treatment sessions that are necessary to help patients achieve a recovery from their symptoms. About a year of treatment (58 sessions) is needed to produce symptomatic recovery for 75% of patients (Kopta, Howard, Lowry, & Beutler, 1994). While brief psychotherapy may be of help to many, these data suggest that longer-term psychotherapy may still be needed for other patients to reach full recovery. Other community-based studies of psychotherapy examine the extent to which treatments developed and tested under ideal conditions in academic settings can be exported to the types of therapists and patients who participate in psychotherapy in community settings.

PSYCHOTHERAPY EFFECTIVENESS

Psychotherapy effectiveness means that psychotherapy can accomplish its intended or expected result. To be effective, psychotherapy must reliably produce a desirable outcome in the treatment of emotional, behavioral, and/or cognitive dysfunctions.

More research on the effectiveness of psychotherapy is being conducted currently than ever in the history of psychotherapy. A number of factors have spurred interest in psychotherapy research, including the maturation of the field of psychotherapy, increasing acceptance of mental health treatment (resulting in a greater demand for services), and changes in the economics of health care that have caused payers to demand more accountability about the effectiveness of providers' treatments. A great demand exists to evaluate the effectiveness of psychotherapies based upon objective information derived from controlled studies as opposed to the opinions of professionals.

Background of Psychotherapy Effectiveness

In the past, many researchers have questioned the effectiveness of psychotherapy. In 1952, Hans Eysenck investigated whether psychotherapy was an effective treatment by studying the outcome data for 8,053 clients reported in 24 research articles. His key dependent measures were discharge data from New York Hospital and improvement from patients seeking insurance settlements. Eysenck's results showed that two thirds of all neurotics who entered psychotherapy improved within 2 years, but two thirds of neurotics who did not enter therapy also improved (Eysenck, 1952). In a review of additional studies, Eysenck reached the general conclusion that patients who received psychotherapy fared no better than control subjects. Eysenck's claim that no conclusive evidence showed that psychotherapy with neurotics was more effective than no psychotherapy stirred controversy and stimulated interest in answering the fundamental research question, Is psychotherapy beneficial and effective?

Numerous investigators reanalyzed the original research upon which Eysenck based his conclusions and found greater rates of improvement in the therapy samples and a lower rate of spontaneous remissions in the control subjects. New interpretations of Eysenck's data led authors to conclude that the results of psychotherapy are positive, with a minority of patients showing no improvement or deterioration. As the controversy evolved, the scientific community of psychotherapy researchers more closely scrutinized the methodology used to evaluate the effectiveness of therapy and recognized that while rigorous scientific assessment of psychotherapy was necessary, it was also complex. In order to draw valid conclusions about the effectiveness of psychotherapy, multiple factors needed to be controlled. Researchers were challenged to try to find a universal, standardized definition or operational definition of psychotherapy; to use methodological strategies for measuring outcomes that are reliable and valid; and to resolve ethical issues about withholding treatment. The following variables needed to be controlled: The nature of the sample; amount and quality of therapy; nature and onset of duration of pathology; preciseness of the definition of disorders; comparability of cases across studies; duration and rigorousness of follow-up; patient, therapist, and process variables; and independent outcome assessments.

As methodological sophistication increased, researchers developed meta-analysis, a quantitative procedure that allowed them to examine the statistical significance of the size of effects across multiple psychotherapy studies and to draw conclusions about aggregate results. Smith and Glass (1977) conducted the first meta-analytic study of significance, in which they reviewed 475 studies, computed an effect size statistic, and concluded that those who received psychotherapy were better off than 80% of those who received no treatment. Other meta-analytic studies were conducted and based upon numerous reviews of the literature using both traditional and meta-analytic approaches, researchers concluded that psychotherapy is helpful and has clinically significant effects. Not everyone benefits from psychotherapy and some even suffer from iatrogenic or negative effects, but planned, systematic efforts of trained therapists to relieve psychological distress were more effective than placebo control groups, waiting lists, or no treatment control groups, and patients who showed initial changes in therapy generally maintained the changes.

Once it was established that there were general positive effects of psychotherapy, the next question posed was "Which psychotherapeutic technique is most effective?" Overall, there is no clear evidence to show that one therapy is superior over another over the long term. Some studies show that some specific techniques (behavioral, cognitive, eclectic) are helpful in the treatment of specific circumscribed behaviors such as stuttering, phobias, compulsions, childhood aggression, or sexual problems. Thus, the most current thematic research question is "What are the specific effects of specific interventions by specific therapists on specific symptoms or patient types?"

While the available research measuring the effectiveness of psychotherapy varies in quality, with earlier research being less scientifically rigorous than more recent research, the methodology has improved continuously so more recent studies meet more stringent criteria. As more and more studies are conducted to test the effectiveness of psychotherapy, hopefully more rigorous scientific parameters are applied. The gold standard or ideal efficacy study methodology is one that contrasts one type of therapy with a comparison group under well-controlled conditions and thus empirically validates the therapy. In such an ideal study, patients are randomly assigned to treatment and

control conditions, controls are rigorous, treatments are manualized, patients are seen for fixed periods, target outcomes are well operationalized, and raters and diagnosticians are blind to patient assignment (Seligman, 1995). The trend toward the empirical validation of modern psychotherapy is growing, with increasing numbers of studies showing that the effectiveness of psychotherapy is a good measure of psychotherapy's worth.

PSYCHOTHERAPY RESEARCH

Psychotherapy research is concerned primarily with the evaluation of the impact and process of psychological interventions across various forms of treatment (e.g., individual, couple, group) for clinical disorders (e.g., depression), problems of living (e.g., marital discord), and medical conditions (e.g., chronic pain). It is also concerned with characteristics of the client and therapist as they relate to the process and outcome of treatment.

Psychotherapy Outcome

With regard to outcome, more than 50 years of research has shown that psychotherapy works: It is more effective than the absence of treatment, placebo, and pseudotherapies (Lambert & Bergin, 1994). Based on the findings of controlled clinical trials (e.g., Chambless & Hollon, 1998), researchers have been able to identify a large number of empirically supported treatments (ESTs) for specific clinical problems experienced by adults, adolescents, and children (see Kendall & Chambless, 1998). However, with the exception of a number of specific problems and related treatments (e.g., cognitive-behavioral therapy for Panic Disorder), comparative outcome research suggests that the impact of different forms of psychotherapy tends to be equivalent (Lambert & Bergin, 1994).

Although psychotherapy works, there are clear limitations to its impact. For example, even though the EST movement demonstrates that a large number of individuals can benefit from psychotherapy when applied in controlled clinical trials, it is not clear how these findings might generalize to clinical practice in natural settings. In addition, a number of clients terminate treatment prematurely, do not respond to therapy, and/or even deteriorate (Garfield, 1994). As a strategy to increase the beneficial impact of treatment, therapists have attempted to integrate or selectively prescribe techniques associated with different therapeutic orientations (Castonguay & Goldfried, 1994). However, with just a few notable exceptions (see Glass, Victor, & Arnkoff, 1993), these integrative efforts have yet to receive considerable empirical attention.

Psychotherapy Process

Whereas outcome research focuses on whether or not psychotherapy works, process research investigates how it works (or fails to work). Researchers (see Beutler, Machado, & Allstetter Neufeldt, 1994; Garfield, 1994; Orlinsky, Grawe, & Parks, 1994) have studied process variables related to the *therapist* (e.g., adherence to treatment manuals), *client* (e.g., emotional experience), *client–therapist relationship* (e.g., working alliance), and *structure of treatment* (e.g., duration of therapy). Examination of such variables, among many others, is in line with the two main goals of process research: (1) describing what happens in treatment, and (2) identifying factors that foster or impede client improvement.

With respect to the descriptive function of process research, several studies have shown that therapists can adhere to treatment protocols and that different forms of treatment can be discriminated based on the therapist's use of prescribed techniques (e.g., DeRubeis, Hollon, Evans, & Bemis, 1982; Hill, O'Grady, & Elkin, 1992). However, studies have also demonstrated that there are important differences between what therapists do and what they say they do. For example, just as psychodynamic therapists have been shown to apply supportive interventions presumably more native to behavior therapy (e.g., prescription of daily activities; Wallerstein & Dewitt, 1997), behavior therapists have also been shown to demonstrate higher levels of empathy than psychodynamic therapists (Sloane, Staples, Cristol, Yorkston, & Whipple, 1975).

With regard to its function of identifying helpful and hindering aspects of treatment, process research has uncovered a number of variables that have been linked positively with outcome (Orlinsky et al., 1994). Among them, the quality of the therapeutic alliance has shown to be the most robust predictor of improvement (Constantino, Castonguay, & Schut, 2002). According to Lambert (1992), common factors (such as the alliance) and placebo effects account for approximately 45% of the variance in therapy outcome.

Process research has also provided support for the therapeutic importance of variables assumed to be unique to particular approaches. For example, the use of homework has been linked to improvement in cognitive therapy (CT;

e.g., Burns & Nolen-Hoeksema, 1991). On the other hand, researchers have found other techniques prescribed by the CT manual to be either unrelated to or negatively associated with improvement (e.g., Castonguay, Goldfried, Wiser, Raue, & Hayes, 1996). Similar mixed findings with regard to prescribed interventions have also been found in other forms of treatment (e.g., psychodynamic, see Schut & Castonguay, 2001).

Client and Therapist Characteristics

Psychotherapy researchers have also been interested in examining characteristics of clients and therapists. A large number of demographic variables have been investigated (e.g., age, ethnicity), but none of them appear to account for a significant part of the outcome variance (Beutler et al., 1994; Garfield, 1994). However, a number of other client and therapist characteristics have been shown to relate to psychotherapy process and outcome. For example, in different forms of psychotherapy for depression, clients' pretreatment level of perfectionism has been negatively related to the therapeutic alliance and outcome (e.g., Blatt, Quinlan, Pilkonis, & Shea, 1995). Also negatively related to outcome is the therapist's level of emotional disturbance and distress (Beutler et al., 1994). Moreover, Henry, Schacht, and Strupp (1990) have found that the therapist's hostility toward self is predictive of negative process in the client–therapist relationship.

Studies have also examined whether the matching of client, therapist, and/or treatment variables could improve the impact of therapy. With few exceptions, however, this research has lead to a paucity of reliable findings. Among these exceptions is the work of Beutler et al. (1991), who demonstrated that clients with an externalized coping style improved more in a symptom-oriented treatment (i.e., CT) than clients with an internalized style of coping who responded most to an insight-oriented treatment (i.e., supportive/self-directive therapy [S/SD]). Beutler et al. (1991) have also found that whereas clients high in reactance level (those who resist being controlled by others) fare better in a nondirective type of treatment (i.e., S/SD) than in directive forms of therapies (i.e., focused-expressive therapy and CT), clients low in reactance respond more to CT than S/SD.

Conclusion

Research has offered considerable information with regard to the impact and process of psychotherapy. Moreover, this information is being further refined with the emergence of more sophisticated methods to assess treatment processes (e.g., task analysis; Rice & Greenberg, 1984). Presently, however, it seems fair to say that psychotherapy research has had a limited impact on clinical practice. For example, although the current ESTs represent for many researchers the embodiment of the scientific-practitioner model, they are perceived by many clinicians as irrelevant academic efforts, if not major threats to valid clinical practice (see Castonguay, Schut, Constantino, & Halperin, 1999). Fortunately, efforts to bridge the gap between researchers and clinicians have begun to emerge (Newman & Castonguay, 1999), which holds the promise of improving the effectiveness of psychotherapy and better understanding its process of change.

PSYCHOTHERAPY TRAINING

Psychotherapy training has two aspects. One concerns the models of training in graduate programs, while the second aspect focuses on the way in which psychotherapy is learned.

Training Models

Since the end of World War II, a number of conferences (often known by the location where they were held, such as the Boulder, Vail, Swampscott, or Norman conferences) and articles emanating from these conferences have defined models of clinical, counseling, and community psychology training programs. These models usually invoke an image of training that weaves together didactic and applied competencies. The didactic components include mastering research and statistical analysis as well as basic processes such as learning, cognition, psychopathology, and psychophysiology. The applied components include interviewing, assessment, and psychotherapy. David Shakow (1969) developed a model curriculum in which the student begins clinical training concurrently with his or her didactic studies. The student's initial exposure to clinical work might take the form of sitting in with experienced interviewers, assessors, and psychotherapists. In subsequent years the student usually takes on more responsibility in assessment and psychotherapy, still under the supervision of more senior clinicians, while simultaneously progressing through the didactic studies. Shakow's hope was that the student would then structure a thesis (for the master's degree) or a dissertation (for the PhD) that was methodologically sound and clinically important. Such clinically relevant research takes time to come to fruition.

Regrettably, implementation of the Shakow model has become weakened by several forces. First, academic psychologists find greater likelihood of rewards (promotion, tenure, and grants) from conducting research that might be more methodologically driven and fewer rewards for supervising clinical activities (Hess & Hess, 1983). Thus the student's clinical activities are not as valued in the advisor's eyes to the same degree as pure research endeavors. Similarly, clinicians in the field who might have been receptive to research in past decades are now pressed to spend more of their time generating third-party payments. Clinical research detracts from their fee-bearing activities. These two forces account for some of the division of the academic from the clinical that was of one cloth in the Shakow model.

Manuals that detail psychotherapeutic treatment of defined problems are suppose to increase the effectiveness of psychotherapy in this era of managed care and attention to the "bottom line." For well-defined and common problems during research trials, both experienced and relatively inexperienced professionals can use manuals effectively. However, manualized treatment is far from universally ac-

cepted. Critics argue that this approach stifles the therapist's exploration of the patient's life, which may cause therapists to miss important underlying problems that may accompany the presenting complaint. Indeed, Lehman, Gorsuch, and Mintz (1985) found that most presenting complaints mask the real problem for which the patient is seeking treatment.

Psychotherapy effectiveness studies continue to show that there are salutary effects to therapeutic interventions. (Seligman, 1995; Smith & Glass, 1977). These effects seem to be related to the therapist's style and personality ("nonspecific" therapy factors) more than to a particular theoretical bent or persuasion of the therapist. Again influence by managed care, recent research efforts focus on therapeutic efficacy; that is, getting the highest dose-effect benefit possible to cut spiraling costs of patient care, irrespective of the client's needs.

The advent of the PsyD, or doctorate of psychology, degree-granting programs has been another influence on psychotherapy training. PsyD programs emphasize hands-on training rather than the research and basic processes approach of the PhD programs. Before a student can earn the doctorate in either program, the student must complete an internship. The internship exposes the student to a more varied types of clients (adult and child, inpatient and outpatient) with a variety of problems (psychosis, anxiety disorders, personality disorders, and medical conditions with psychological sequelae). Some professionals feel that competence in psychotherapy develops only after a minimum of five years of postdoctoral clinical work, during which the student-psychotherapist can see changes in a number of patients' lives over time and learn how his or her skills affect people.

Psychotherapy Supervision

Psychotherapy supervision is the modality by which students learn psychotherapy. Hess (1980) summarized the models of supervision that include the supervisor in the roles of lecturer, teacher, peer, monitor, learned elder, and therapist. A number of theories postulate stages through which the student psychotherapist is presumed to pass. These include the demystification of psychotherapy, the acquisition of technical skills, and the beginning of mastery of complex skills and judgments, such as timing of interventions and tailoring techniques to the particular patient. Similarly, supervisors are presumed to pass through stages en route to becoming accomplished supervisors. Swain (1981) found that supervisors perceive supervisee performance along five dimensions: (1) clinical sense, as exemplified by listening skills, maintaining poise, and allowing the client to make decisions; (2) preparation for supervision and psychotherapy, such as organizing materials before sessions; (3) theoretical and cognitive knowledge, such as the ability to relate clinical material to theoretical concepts; (4) self-awareness and appropriate disclosure, such as access to feelings about patients that can be discussed in supervision; and (5) boundary management, as shown by being on time for appointments, knowing clinical rules, and attending to record keeping. Aldrich (1982) found that students regard supervisors along eight stable dimensions: defensiveness, professionalism, experience as a clinician, theoretical base, experience as a teacher, appropriate interest in the supervisee's life, likeableness, and ability to motivate.

In recent years, more attention has been devoted to models of supervision, to an interpersonal theory of supervision, and to qualitative research (Watkins, 1997). The small number of supervisees in any particular setting and the competing demand for service fee generation hinder efforts to conduct nomothetic and quantitative research. Research concerning models of supervision, effectiveness of intervention and learning strategies, and assessment of changes as a function of supervision in both the neophyte psychotherapist and his or her clients needs to be conducted. Nonetheless, the qualitative research that is emerging shows how supervisors benefit psychotherapists-in-training (Ladany & Muse-Burke, 2001).

Table 1. Summary of Four Factors in the Mediation of Teacher Expectancy Effects

Factor	Brief Summary of the Evidence
Central Factors	
Climate (affect)	Teachers appear to create a warmer socioemotional climate for their "special" students. This warmth appears to be at least partially communicated by nonverbal cues. (Estimated effect size $r = .29$).
Input (effort)	Teachers appear to teach more material and more difficult material to their "special" students. (Estimated effect size $r = .27$).
Additional Factors	
Output	Teachers appear to give their "special" students greater opportunities for responding. These opportunities are offered both verbally and nonverbally (e.g., giving a student more time in which to answer a teacher's question). (Estimated effect size $r = .17$).
Feedback	Teachers appear to give their "special" students more differentiated feedback, both verbal and nonverbal, as to how these students have been performing. (Estimated effect size $r = .10$).

Note: Even the smallest effect size *r* listed above reflects a difference in performance levels of 55% versus 45%; the larger effect size *r*s listed above reflect a difference in performance levels of 64% versus 36%.

PYGMALION EFFECT

The term *Pygmalion effect* refers broadly to the effects of interpersonal expectations, that is, the finding that what one person expects of another can come to serve as a self-fulfilling prophecy. These effects of interpersonal self-fulfilling prophecies have come to be called *Pygmalion effects* in general, but especially so when the interpersonal expectancy effects occur in an educational context.

Early Laboratory Experiments

The earliest studies of Pygmalion effects were conducted with human participants. Experimenters obtained ratings of photographs of stimulus persons from their research participants, but half of the experimenters were led to expect high photo ratings and half were led to expect low photo ratings. In the first several such studies, experimenters expecting higher photo ratings obtained substantially higher photo ratings than did experimenters expecting lower photo ratings.

To investigate the generality of these interpersonal expectancy effects in the laboratory, two studies were conducted employing animal subjects. Half of the experimenters were told that their rats had been specially bred for maze (or Skinner box) brightness and half were told that their rats had been specially bred for maze (or Skinner box) dullness. In both experiments, when experimenters had been led to expect better learning from their rat subjects, they obtained better learning from their rat subjects (Rosenthal, 1966, 1976).

Pygmalion Effects in the Classroom

Researchers hypothesized that if rats became brighter when expected to by their experimenters, then perhaps children could become brighter when expected to by their teachers. Accordingly, all of the children in one study were administered a nonverbal test of intelligence, which was disguised as a test that would predict intellectual "blooming." The test was labeled "The Harvard Test of Inflected Acquisition." There were 18 classrooms in the school, three at each of the six grade levels. Within each grade level the three classrooms were composed of children with above average ability, average ability, and below average ability, respectively. Within each of the 18 classrooms, approximately 20% of the children were chosen at random to form the experimental group. Each teacher was given the names of the children from his or her class who were in the experimental condition. The teachers were told that these children's scores on the "Test of Inflected Acquisition" indicated that they would show surprising gains in intellectual competence during the next 8 months of school. The only difference between the experimental group and the control group children, then, was in the mind of the teacher.

At the end of the school year, 8 months later, all the children in the school were retested with the same nonverbal test of intelligence. The children from whom the teachers has been led to expect greater intellectual gain showed a significantly greater gain than did the children in the control group (Rosenthal & Jacobson, 1968, 1992).

Domains Investigated

A dozen years after the Pygmalion effect classroom study was completed, the research literature on interpersonal expectancy effects had broadened to include 345 experiments that could be subsumed under one of eight domains of research: human learning and ability, animal learning, reaction time, psychophysical judgments, laboratory interviews, person perception, inkblot tests, and everyday situations (Rosenthal, 1991). After another dozen years, the overall mean effect size of the 479 studies was found to be an *r* of .30. An *r* of that magnitude can be thought of as the effects of interpersonal expectations changing the proportion of people performing above average from 35% to 65%.

The Four-Factor Theory

A considerable amount of research has been summarized, employing meta-analysis, that suggests how teachers may treat differently those children for whom they have more favorable expectations. Table 1 summarizes these differences as four factors, two that are primary and two that are somewhat smaller in their magnitude of effect (Harris & Rosenthal, 1985).

Current Research

The most recent work, and that currently in progress, continues to examine the effects of interpersonal expectancies in an ever widening circle of contexts. Pygmalion effects in management, courtrooms, nursing homes, and a variety of classrooms are under investigation. It has been shown that organizational effectiveness can be increased by raising leaders' expectations, that juries' verdicts of guilty can be increased by assigning them judges (to instruct them) who believe the defendant to be guilty, that the depression levels of nursing home residents can be reduced by raising the expectation levels of caretakers, and that teacher expectations can serve as self-fulfilling prophecies in other countries and for more than simply intellectual tasks. In all these cases the mediating variables are receiving special attention, with rapidly growing evidence that much of the mediation is occurring by means of unintended nonverbal behavior (Ambady & Rosenthal, 1992; Babad, 1992; Eden, 1990).

Q

Q-SORT TECHNIQUE

The Q-sort technique is a general method for eliciting a detailed, subjective description of a stimulus. This description is quantitative and based on explicit, internal reference points. The letter *Q* was used by the inventor of the technique, Stephenson (1935, 1936), to indicate the affinity of the data provided by the technique for use in Q-type analyses (based on correlations between persons, in contrast to R-type analyses based on correlations between variables). The Q-sort technique is used for two quite distinct purposes: First, as originally devised by Stephenson, the technique is a broadly applicable scaling method that can articulate the personal subjective understanding and experience of the respondent in great detail. Alternatively, when respondents describe the same stimulus, intersubjective agreement across descriptions provides a basis for drawing inferences about the stimulus. In the former approach, the focus is on the perceiver; in the latter approach, the focus is on the perceived. The perceiver-focused approach is utilized most often in studies of social and political attitudes that are conducted in political science (see Brown, 1980, for a detailed account of this approach, and McKeown and Thomas, 1988, for a more concise survey). The second approach, predominant in psychology, follows Block's (1961) adaptation of the method for personality assessment. In this application, the stimulus is a target person who is typically described by multiple judges who are acquainted with the target.

Q-Sort Procedure

The Q-sort method requires a set of items that might be used to describe any member of a class of stimuli. The respondent, or judge, sorts the items (typically words or phrases printed on separate cards) into ordered categories ranging from extremely characteristic of the target stimulus to extremely uncharacteristic of the target stimulus. The number of items that may be placed in each category is fixed, and each category has a preassigned numerical label that becomes the score of the items placed in that category. A rank ordering of items can be viewed as an example of the Q-sort method, in which the number of items and the number of categories are equal in number. More typical is the California Adult Q-Set (Block, 1961), which contains 100 items to be sorted into 9 categories to form a quasi-normal distribution (the number of items to be placed in categories 1 to 9, respectively, are 5, 8, 12, 16, 18, 16, 12, 8, and 5).

The fixed distribution of the Q-sort forces the judge to identify which items are most and least descriptive of the target person relative to the other items in the Q-set. Thus, if the Q-item is "friendly toward strangers," the judge compares the degree to which this item is an apt description of the target, compared to the other items. This is in marked contrast to the typical procedure in which judges would be asked whether the target, when compared with others, is friendly toward strangers. Ratings obtained using the explicit internal frame of reference created by the use of a fixed distribution were labeled *ipsative* by Cattell (1944) to distinguish them from the more usual normative ratings.

The ipsative character of the Q-sort is the source of both strengths and limitations of the method (Ozer, 1993). Among the benefits are that it encourages the judge to apply considerable thought and effort to the numerous judgments, and removes judge differences in the distribution of ratings, thereby controlling for certain types of judge error and bias. Nonindependence among the item placements is the source of specific problems with Q-sort method. Mean item differences across groups or in the same group over time are difficult to interpret (Ozer & Gjerde, 1989). Ipsativity also presents difficulties for statistical procedures that assume independence among items (Clemans, 1966).

Types of Q-Sets

In Stephenson's (1953) description of Q-methodology, Q-items were construed as members of a population that are sampled for use in particular studies. Block (1961) identified both practical and scientific reasons for the use of a standard set of items to compose a particular Q-set. Numerous Q-sets have been developed for various purposes, but in general there are two broad types of item domains. Some Q-sets define a broad domain of item content and have relatively little redundancy among items. For example, Block's (1961) California Adult Q-Set provides near-comprehensive coverage of personality. Other Q-sets focus on a much narrower range of content and assess just a few, or even one, primary construct. The Attachment Q-Set (Waters & Dean, 1985), which includes content clusters for particular attachment styles, is a well-known example of this second approach.

Evaluation and Use of Q-Sort Data

When judges' descriptions of target stimuli are used to make inferences about the target, it is important to establish that there is substantial agreement among judges. Either the average item reliability or the average reliability of each target description is typically computed for this purpose (see Block, 1961; Ozer, 1993). The composite judge evaluations may be analyzed like any other rating data, but they also invite application of other sorts of analyses based on either the correlation between persons or the correlation between the description of the same person over multiple occasions. Such methods have been employed with some frequency in personality psychology, where correlations between the Q-sorts of different persons have been used to develop taxonomies of personality (e.g., Block, 1971); correlations between different Q-sort descriptions of the same person at different ages have been used to assess personality consistency and change (e.g., Ozer and Gjerde, 1989).

QUALITY OF LIFE

Quality of life has become a popular concept that is used by politicians, marketing executives, media and sports personalities, and members of the public. There is an extensive scientific literature on the subject by health practitioners and social scientists. Scholars in ancient China and Greece were interested in quality of life, and renewed interest in it occurred in times of enlightenment in the centuries that followed. In recent history, quality of life emerged as a political entity in the United States in the 1950s and in Europe in the 1960s. Several U.S. presidents, such as Eisenhower, Johnson, and Nixon, popularized the term in presidential commissions and in their speeches. The focus on quality of life in the last half century has increased because there has been a general recognition that the health of countries must be judged in something more than gross economic terms and that the health of individuals is something beyond the absence of illness.

The economic focus led to the development of social indicators directed at objectively measuring the quality of life of populations. In 1970 the Organization for Economic Cooperation and Development (OECD) encouraged member countries to develop and report measures of social well-being for their constituents. This resulted in a number of countries reporting such social indicators as the number of schools per person, the number of hospital beds per person, and the number of health care professionals per person. It soon became apparent that, while social indicators provided information about cultural entities (towns, states, and countries), they provided little or no information about the quality of life of individuals within these entities. This prompted researchers in a number of countries, including the United States, Canada, Europe, and Australia, to assess the subjective or perceived quality of life of population samples within their countries. Perhaps the earliest such study was by Bradburn in 1969. He surveyed two samples ($N = 2{,}787$ and $N = 2{,}163$) from several metropolitan areas in the United States. The measure he employed was the effect balance score, which was based on ratings of positive and negative effect. It was assumed to be indicative of quality of life. Campbell, Converse, and Rogers carried out a second important study in the United States in 1976. They sampled 2,160 individuals selected to be representative of the national population. Participants were asked to rate their satisfaction in a number of life domains and to rate their satisfaction with their life as a whole. Subsequent to these early cross-sectional studies, the methods of assessing quality of life in the population at large have become more complex.

In 1947 the World Health Organization promulgated a definition of health that suggested that health was not just the absence of illness, but was also a state of physical, psychological, and social well-being. This definition provoked health professionals to start to view the impact of their interventions in a context broader than just symptom recov-

ery. Thus, in the last three decades, there has been a proliferation of what have come to be known as Health Related Quality of Life (HRQOL) measures. Global and specific HRQOL measures have been developed in most branches of health care, including cardiology, cancer, epilepsy, urology, psychiatry, and general medicine, to name just a few. One of the most ambitious projects is that of the World Health Organization Quality of Life Group (1998), who are developing a global health measure of quality of life that can be employed with people from differing cultures worldwide.

Despite the popular and scientific interest in quality of life, there is little agreement on what is meant by the term *quality of life.* As Evans (1997) noted, quality of life has been used interchangeably with well-being, psychological well-being, subjective well-being, happiness, life satisfaction, positive and negative affect, and the good life. There is in fact a high degree of similarity among many of these measures, and statistical analyses with samples of the general population indicate that measures of life satisfaction, positive and negative affect, and quality of life are highly related to each other and form a single factor (Evans, 1997). Most researchers in the field believe that quality of life is a multidimensional concept, and there is fair agreement as to the majority of subdomains within the construct. There is some disagreement concerning the method by which measures in each of the subdomains should be aggregated to form an overall measure of quality of life.

The quality-of-life area has an abundance of measures and a paucity of theoretical models. Two prominent models are the bottom-up and top-down models of quality of life. Proponents of the top-down model argue that our general quality of life influences quality of life in the specific domains of our life, hence the focus of research should be on these global measures. Those who advocate the bottom-up model propose that the quality of our life in each life domain affects our overall quality of life, thus the specific domains should be the focus of research. Another current line of research is the identification of factors that influence an individual's quality of life. There is increasing evidence that personality dimensions, such as self-esteem, locus of control, extraversion, neuroticism, and hardiness, to name but a few, influence an individual's quality of life. This network of relationships could form the basis for a more elegant theory in the field. Recent attempts to measure quality of life across the many cultures around the world also have potential to provide some of the parameters that would define a quality-of-life theory. Emphasis in the future will be on the development of quality-of-life theoretical models, which will inform current measurement issues.

QUESTIONNAIRES

Questionnaires are inventories used to gather various kinds of information. Questionnaires are typically self-administered, self-report devices and are similar to interviews (face to face or over the telephone). Among the advantages of questionnaires are their relatively low cost as a means of gathering data, a general freedom from bias on the part of an interviewer, the large number of individuals who may be asked to respond, the sense of anonymity that respondents may feel, the temporal flexibility afforded the respondent, the possibility of directly linking research questions and survey results, the relative economy of data collection, and the ease of data coding and analysis for interpretation of the results (Kidder, 1981). One disadvantage of questionnaires relates to return rates; frequently, only a small fraction of those provided with a questionnaire complete it. Also, respondents may not be honest or may permit subtle biases to influence their responses. Furthermore, many Americans are still unable to read and write well enough in English to complete a questionnaire.

Questionnaires are used in both basic and applied research and in either experimental or correlational research. For example, many psychologists who investigate personality use survey questionnaires, and surveys may also be used as dependent variables in experiments. In applied research, questionnaires are often used in program evaluations, job analyses, needs assessments, and market research. These include personality variables, attitudes, values, beliefs, interests, and descriptions of past and present behavior. Furthermore, because most questionnaire research is correlational, causal attributions are generally inappropriate. However, it is the experimental design, rather than the nature of the variable per se, that dictates the ability to make causal statements.

Types of Questionnaires

Most questionnaires are composed of numerous questions and statements. Statements are frequently used to determine the extent to which respondents agree or disagree with a given thought, concept, or perspective. This agree-disagree format is often referred to as Likert scales, after the industrial psychologist Rensis Likert who pioneered their use and analysis. Survey questions may be of two general

types: free response or response selection. Free-response questions are often open ended; response-selection questions are close-ended or fixed-alternative questions. Chief advantages of response-selection questions are ease of response and of data entry for data analysis. Answers to free-response questions, on the other hand, must first be categorized, scored, and coded. Because this process often demands a trained professional, the process is inevitably time consuming as well as expensive. Furthermore, respondents may find detailing their answers in writing to be laborious and may choose not to respond or to give short, inadequate responses.

There are a number of steps involved in developing a questionnaire properly. An example listing of these steps follows: specifying the objectives of the study, designing the questionnaire itself, drafting it, editing it, developing instructions for it, pretesting it, revising it, developing a sampling plan for administering it, executing the survey-data collection, data analysis, and reporting the results. Only a few of these steps are mentioned below.

The goals of the study be detailed; such work may lead to the elimination of unnecessary items and result in a higher response rate. The objectives then form an outline of the questionnaire. Once topics for questions are provided, decisions regarding the best item formats may be made (e.g., free-response or response-selection questions). Bouchard (1976) reported that questionnaire construction is still primarily an art form, and Bouchard provided various general rules based on both research and experience that may improve questionnaire construction.

Both introductions and instructions are advisable. Good introductions increase the rate of returned questionnaires. Some researchers send postcards to potential respondents in advance of the survey advising them of the survey. Cover letters that explain the purpose and importance of the questionnaire are strongly recommended. Instructions should be clear and as simple as possible. If the survey is to be returned in the mail, a stamped, addressed envelope should be included.

Pretesting the questionnaire is essential. Interviews with or written comments from respondents may highlight potential difficulties that may be avoided. Occasionally, when many respondents specify "other" responses to certain response-selection questions, new options can be added.

Statistical analyses used for other psychological measures (interitem correlations or reliability and validity studies) are frequently appropriate for questionnaires.

Two recurring problems in questionnaire research are response biases and nonrespondents. In many studies, respondents either avoid threatening questions or try to make themselves seem better; this latter response style is known as social desirability. Bradburn, Sudman, & associates (1980) make a number of recommendations to reduce this effect. Explanatory introductions to threatening questions help, as do promises of confidentiality. Permitting respondents to write sensitive answers rather than simply checking an answer is also beneficial. Another potentially useful strategy is asking respondents to describe friends or "people like themselves" rather than themselves.

Increasingly, questionnaires are being used in cross-cultural research. In such cases, the translation of a questionnaire from one language to another is required. Cautions need be involved in such instances, especially because language and culture must both be addressed (Geisinger, 1994).

Achieving an adequate and unbiased sample is perhaps the biggest concern in questionnaire research. The nonresponse problem is twofold. First, many individuals do not respond to surveys. Furthermore, nonrespondents frequently differ from respondents. Strategies to increase return rates help include appeals and offers of small rewards, for example. Another approach is to interview a random sample of nonrespondents.

Because of their relative ease, low cost, and low-intrusion value, questionnaires are certain to continue to be frequently used as data-collection devices in psychology. Solutions to problems such as those mentioned are likely to be sought. Even if good solutions are found, it is unlikely that experimental methodology will relinquish its preeminent status in psychology since causal relationships are more easily discerned with it. Nonetheless, questionnaire use is increasing, and this growth will likely continue.

R

RACISM

The term *racism* is a relatively recent one that dates back only to 1936. Although many definitions of racism have been proposed, an all-inclusive definition has yet to be agreed upon, particularly as researchers have identified a variety of racisms (Richards, 1997). Moreover, different levels of analysis have been adopted to study racism, including individual, interpersonal, intergroup, and institutional approaches (Augoustinos & Reynolds, 2001).

Central to many definitions of racism is the belief in a biological hierarchy between racial and ethnic groups, as well as associated social practices that maintain and reproduce different status positions of groups based on such beliefs. The belief that differences between social groups are biologically driven implies that such variability is fundamental and fixed. These essentialist beliefs lead to the categorization of people into groups based on assumptions that surface characteristics (e.g., skin color) reflect deeper essential features, and these in turn are believed to be inherent and unchangeable and to reflect the real nature of the groups they represent. It has been argued, however, that contemporary racism—commonly referred to as the *new racism*—is less about beliefs in a biological hierarchy between groups and increasingly about beliefs in the cultural superiority of a dominant group's values, norms, and practices. Another variant of contemporary racism rejects the notion of a cultural hierarchy altogether and instead emphasizes the need and desirability of the separate development of groups, claiming that it is not in human nature for us to coexist peacefully with culturally different others.

There has been a tendency within psychology to use the terms *prejudice* and *racism* interchangeably. Jones (1997), however, makes the case that racism is distinct from prejudice. Prejudice has commonly been defined as negative attitudes and behavior toward a social group and its members. Prejudice is typically regarded as an individual phenomenon, whereas racism is a broader construct that links such individual beliefs and behavior to broader social and institutional norms and practices that systematically disadvantage particular groups. The second important difference between prejudice and racism relates to the role of power. At an individual level, a person can display prejudice, but this in itself does not necessarily constitute racism. Central to racism is the ability of dominant groups systematically to exercise power over outgroups. It is important that the power one group has over another transforms prejudice into racism and links individual prejudice with broader social practices (Jones, 1997).

Practiced at a structural and cultural level, racism maintains and reproduces the power differentials between groups in the social system (Jones, 1997). Racism practiced at this broad societal level has been referred to as institutional and cultural racism. Institutional racism refers to the institutional policies and practices that are put in place to protect and legitimize the advantages and power one group has over another. Institutional racism can be overt or covert, intentional or unintentional, but the consequences are that racist outcomes are achieved and reproduced. Cultural racism occurs when the dominant group defines the norms, values, and standards in a particular culture. These mainstream ideals permeate all aspects of the social system and are often fundamentally antagonistic with those embraced by particular minority groups (e.g., African Americans in the United States). In order to participate in society, minority groups often have to surrender their own cultural heritages and adopt those of the dominant group (e.g., the White majority).

Old and New Forms of Racism

By the early 1970s researchers had discerned a notable change in racial attitudes in the United States and other Western countries. Survey studies were indicating that blunt, hostile, segregationist, and White supremacist beliefs were less openly acceptable to members of the White majority. A distinction began to be made between old-fashioned racism, which is blunt, hostile, segregationist, and supremacist, and modern or symbolic racism, which in contrast is subtle and covert and, paradoxically, endorses egalitarianism. Modern racism rejects racial segregation and notions of biological supremacy and is instead based on feelings that certain social groups transgress important social values such as the work-ethic, individualism, self-reliance and self-discipline: values that are embodied in the Protestant ethic. Symbolic or modern racism justifies and legitimates social inequities based on moral feelings that certain groups violate such traditional values.

Other accounts of the new racism include ambivalent racism and aversive racism (Dovidio & Gaertner, 1986).

Both provide similar models of the new racism, positing that contemporary racial attitudes have become complex, contradictory, and multidimensional. In the ambivalent racism model, pro-Black and anti-Black sentiments are seen to coexist within the person and to reflect different value structures held by the individual. Pro-Black attitudes reflect humanitarian and egalitarian values that emphasize equality and social justice, whereas anti-Black attitudes reflect individualism, the Protestant ethic, hard work, individual achievement, and self-reliance. Similarly, the aversive racism model emphasizes the coexistence of a contradictory complex of attitudes: on the one hand, liberal-egalitarian principles of justice and equality, and on the other, a residue set of negative feelings and beliefs about particular groups that are learned early in life and that are difficult to eradicate completely. In both of these accounts, individuals strive to maintain a nonprejudiced image, both to themselves and to others, and struggle unconsciously to resolve the internal psychological ambivalence that is produced by maintaining a contradictory set of attitudes and beliefs. By justifying and legitimizing social inequalities between groups on the basis of factors other than race, members of dominant groups can avoid attributions of racism and thus maintain and protect a nonprejudiced self-image. Contemporary racism is therefore seen as more insidious and difficult to identify because of its subtle and covert nature. This has led to the development of new scales and unobtrusive methodologies to identify and measure this more subtle racism.

These accounts of the new racism tend to locate racism primarily within the psychological and cognitive domain of the individual. One recent approach that emphasizes the ambivalent and contradictory nature of contemporary racism, but explicitly avoids making claims about the psychology of individual perceivers, is discursive psychology (Wetherell & Potter, 1992). Discursive psychology views racism as interactive and communicative and as located within the language practices and discourses of a society. It is through everyday language practices, both in formal and informal talk, that relations of power, dominance, and exploitation become reproduced and legitimated. The analytic site for discursive psychology is the way in which discursive resources and rhetorical arguments are put together to construct different social and racial identities and to provide accounts that legitimate these differences and identities as real and natural. Discursive psychology locates these language practices, or ways of talking, at a societal level, as products of a racist society rather than as individual psychological or cognitive products. The analytic site therefore is not the prejudiced or racist individual, but the discursive and linguistic resources that are available within an inequitable society. This approach has been able to identify how linguistic resources are combined in flexible and contradictory ways to reproduce and justify racist outcomes in modern liberal democracies.

RAPE

Definition

Definitions of rape are varied. However, most jurisdictions currently define rape as nonconsensual completed or attempted vaginal or anal penetration by the penis, hands, fingers, or other objects, or of the mouth by the penis, through the use of force or threats or when the victim is unable to consent (e.g., due to age or illness). Historically, rape was defined as a crime perpetrated by a man against a woman other than his wife. Today, rape of a spouse is a crime in all states and male victims are recognized, but rape of women by men is 10 times more common than rape of men. Therefore, rape is considered a form of gender-based violence. In 8 of 10 cases, rape is perpetrated by someone the victim knows. Most victims are young, between the ages of 12 and 24.

Prevalence

Rape is a major social and public health problem of national-crisis proportions. According to the Bureau of Justice Statistics, rape is one of the most underreported crimes, which makes it very difficult to count. Underreporting is due in large part to the high level of social stigma and shame associated with rape. Women who say they were raped often are not believed and frequently are blamed in some way for the rape. Some segments of society still believe in rape myths (e.g., women deserve to be raped if they dress provocatively), and these beliefs are stronger when the victim of rape is the wife of the perpetrator.

Incidence and prevalence are two ways to measure the frequency of rape. *Incidence* focuses on the number of acts in a given period, often the last year. Some have argued that the use of incidence rates alone to measure rape may disguise rape as an infrequent crime because respondents may feel uncomfortable reporting rape that occurred recently. *Prevalence* rates may be more useful because they focus on the number of people victimized over a longer period of time, commonly the lifetime, without regard to when or how many times. Questions about lifetime prevalence may produce more accurate estimates because they make respondents more comfortable and may be easier for respondents to answer. In addition, studies that use several behaviorally specific questions such as, "Has anyone ever physically forced you to have sexual intercourse without your consent?" (instead of asking, "Were you raped?") have led to more disclosure. The 1995–1996 National Violence Against Women Survey in the United States found a lifetime prevalence of 18% for women and 3% for men. Studies of wife rape have found lifetime prevalence for women between 10% and 14%. The National College Women Sexual Victimization Study estimated that between 1 in 4 and 1 in 5 college women are raped during their college years.

Vulnerability and Risk

Researchers have examined factors that increase vulnerability to victimization and risk factors for perpetrating sexual assault. Vulnerability research seeks to uncover factors that may increase the likelihood for victimization. Although the focus is on victims, identifying vulnerability factors is distinct from victim blaming. Victim blaming mistakenly assigns responsibility for victimization to victims (e.g., if a woman was drunk when she was raped, it is her fault). One of the most often replicated indicators of risk for adult rape victimization is a previous history of child sexual abuse; however, the risk accounted for by this predictor is not large. Drug use, but not alcohol consumption, was found to be causally related to rape in the largest U.S. longitudinal study to date. Aside from gender and age, personal characteristics of victims are not very good predictors of victimization. Some researchers have concluded that risks for adult victimization are best understood as aftereffects of childhood victimization. For example, women who were sexually abused as children may be more likely to use drugs habitually, which in turn increases the likelihood for future victimization. For some women, rape and sexual assault are repeated at different life stages, and evidence suggests that childhood abuse followed by revictimization in adolescence is the most provocative pattern for future sexual assaults. In sum, the key factors associated with rape victimization are ones over which victims have no control: being young, female, and having a previous history of sexual abuse.

Risk for perpetration is more important to understand than vulnerability to victimization, as victims will exist as long as perpetrators keep offending. Many single-factor theories exist to explain rape perpetration, but rape appears to be complex. A combination of societal, relational, and individual factors including biological and psychological characteristics may be necessary to explain perpetration. The confluence model attempts to do that, proposing that male sexual aggression results from an impersonal-promiscuous orientation to sex, hostile attitudes toward and mistrust of women, and sexual arousal from the domination of women, all of which are shaped by adverse childhood experiences. Many researchers have recognized the important role of societal factors such as patriarchy (the political, economic, and social domination of women by men) in understanding rape perpetration. Research has pointed to factors such as media images (e.g., pornography), sexist attitudes toward women, and male peer support for violence, which, combined with individual factors and previous histories of violence, serve to encourage and legitimate rape perpetration.

Consequences

The physical and psychological impacts of rape victimization are numerous. Immediate physical consequences can include vaginal trauma, broken bones, bruises, sexually transmitted diseases, and pregnancy. Longer term physical health effects also have been found in rape victims, such as chronic pelvic, head, and back pain; gastrointestinal disorders; and high-risk sexual behavior. Immediate psychological consequences may include fear of revictimization, shock, denial, and withdrawal. Ongoing psychological manifestations of rape can include chronic depression, Post-Traumatic Stress Disorder (PTSD), lowered self-esteem, anxiety, sexual problems, suicide ideation and attempts, and alcohol or drug dependency, and these may last for several years. Repeat victims are more likely to suffer from more severe and long-term consequences.

Conclusion

Rape is a ubiquitous problem with serious and long-term consequences. There are always limitations in measuring rape, and neither official crime data nor surveys can by themselves get at the full extent of the problem. Specific and explicit questions are critical in facilitating disclosure of rape, and consistency in questions across surveys is important to compare findings. In order to decrease rape and help victims, it is important to identify and understand risk factors and consequences of rape. More research is needed to measure rape victimization and perpetration across less studied populations such as people of color, gays and lesbians, the homeless, the elderly, and the mentally ill. Understanding the full spectrum of societal-, relational-, and individual-level influences on perpetration is imperative to

inform prevention. Preventive efforts focused specifically on perpetrators are important to eradicate this problem.

RAPID EYE MOVEMENT (REM) SLEEP

The two major phases of sleep are rapid eye movement (REM) sleep and nonrapid eye movement (NREM) sleep (Gillin et al., 2000). REM sleep is often called dreaming (or D) sleep because dreams are reported by about 70–80% of persons awakened during this period. It also has been referred to as paradoxical sleep because the brain paradoxically seems to be in an activated state that is similar to, but not identical to, the waking state. For example, brain metabolism is normal or slightly increased during this period. REM sleep is characterized by an activated electroencephalogram (EEG) pattern (low-voltage, fast-frequency brain waves), muscular paralysis (with the exception of diaphragmatic and ocular muscles), periodic bursts of rapid eye movements, and instability of the autonomic nervous system (e.g., variable blood pressure, heart rate, and respiration). In men, penile erections occur during REM sleep, which can be evaluated in sleep studies to distinguish organic and psychological causes of impotence. Finally, nightmares occur almost exclusively during REM sleep. By contrast, NREM sleep encompasses the other four stages of sleep, including the deepest state of sleep, where the EEG pattern is less activated (high-voltage, slow-frequency brain waves), autonomic function is slower and steadier, brain metabolism is decreased, and there is no muscular paralysis or rapid eye movements. Moreover, less than 30% of persons report dreaming during NREM sleep. For this reason, night terrors (which differ from nightmares) occur during NREM sleep.

The time from falling sleep to the first onset of REM sleep is referred to as REM latency, which is normally about 70–100 minutes and progressively shortens in normal elderly persons to about 55–70 minutes. The amount of REM sleep also tends to decline with age. Approximately 50% of the sleep in babies is spent in REM sleep, which decreases to about 25% by age 4, remains relatively constant throughout adult life, and then begins to decline again after age 60. The number of rapid eye movements during a REM period is referred to as REM density. REM and NREM sleep oscillate throughout the night with a cycle length of approximately 90–100 minutes. The relative proportion of time spent in REM sleep increases during the course of the night while NREM time decreases. Sleep deprivation is normally followed by several nights of increased REM sleep with shortened REM latency, referred to as REM rebound.

Sleep and dreaming have long been an area of clinical and scientific interest in psychology, psychiatry, and neuroscience (Nofzinger et al., 1999). For example, the similarity between hallucinations and the often bizarre and strange content of most dreams naturally stimulated interest in studying REM sleep in patients with schizophrenia and other psychiatric disorders. Although such studies did not support the hypothesis that hallucinations represent waking dreams, further research in depression often found that REM latency is shortened to less than 60 minutes, REM density and the amount of REM sleep are increased, and the distribution of REM sleep is shifted to the earlier part of the night, compared to normal subjects. These findings had been considered a potential biological marker for depression, but shortened REM latency also has been found in some patients with other psychiatric disorders. Patients with schizophrenia and psychotic depression can have extremely short REM latencies, sometimes occurring immediately at the onset of sleep (sleep-onset REM) (Howland 1997). Increased REM sleep and shortened REM latency also occur in patients during the acute period of abrupt withdrawal from alcohol, benzodiazepines, and other sedative-hypnotic drugs. There is some evidence that shortened REM latency might be a genetic marker for depression within families. Many effective treatments for depression (including antidepressant drugs and electroconvulsive therapy) are associated with a decrease (or even suppression) of REM sleep and a lengthening of REM latency. Curiously, total sleep deprivation and even more selective sleep deprivation (i.e., waking patients during the onset of REM sleep throughout the night) has an antidepressant effect in many depressed patients, but this phenomenon is transient, and depression usually returns again after a complete night of sleep.

Abnormalities in REM sleep have been described in two neurologic disorders. In narcolepsy, sleep-onset REM periods are very common. These patients abruptly fall asleep, and they often report hypnogogic hallucinations, which are vivid dream-like states that are likely related to the rapid occurrence of sleep-onset REM periods. Patients with narcolepsy also develop cataplexy, which is the sudden brief loss of muscle tone during waking periods. This may be related to the muscular paralysis normally associated with REM sleep. These findings suggest that narcolepsy is characterized by dysregulated control of REM-NREM sleep. In REM behavior disorder, the normal paralysis of REM sleep is lost. These patients show complex vocal and motor behaviors during REM sleep and often appear to enact the dream content. This is similar to what is seen in animals with selective brain-stem lesions described previously.

Despite many decades of research, the precise function of sleep is not certain (Reiser, 2001). Sleep studies in various animal species suggest that NREM sleep evolved earlier than did REM sleep. These findings and other studies have suggested that NREM sleep might have a primary

role in the conservation and restoration of energy, whereas REM sleep might be especially important to the development and maintenance of cognitive functioning.

RATER ERRORS

Rater errors refer to mistakes made by raters when they use a rating scale to indicate the performance of an individual. The task competence of the rater, as well as the rater's sex, social position, race, religion, and age, have all been found to have effects on the rating given. While many of these errors are idiosyncratic, the following types of rating errors are common across many situations.

The *leniency* error occurs when average ratings tend to be higher than the midpoint of a scale because of pressure on the rater to rate subordinates high, a perception that subordinate rating reflects that of the rater, and the prescreening of students or subordinates before evaluation time. The effect of this error is to reduce variability between individuals. The harshness error is the same situation in reverse.

The *central tendency* error occurs when the rater checks the midpoint of the scale continuously. This can come about because of a hesitancy to "play God" or because extreme ratings (unsatisfactory or poor) require additional support and may have drastic effects on the rater's relationship with the subordinates.

The *halo effect* occurs when one trait affects the way all others are measured. Halo effect implies a positive generalization to other traits; *devil effect* implies a negative one.

The *sequential* error occurs when the particular order of traits has a special effect on the following ones, such as the halo effect.

The *logical* error occurs when a rater correlates specific traits in a manner believed to be consistent with the performance on others. The logical error is more complicated than the halo error.

The *recency* error occurs when an incident close in time to the rating has a greater effect on the rater than it would have had it happened much earlier. This is especially a problem when the incident is an emotional one such as a grievance, accident, or fight.

Rater errors pose special problems for the issues of reliability and validity. Furthermore, ratings that differ in time may accurately reflect a change in behavior even though this difference would demonstrate an artificial lack of reliability. High interrater reliability is a useful tool if both raters are knowledgeable about the individual being rated.

The problem caused by rater error for rating validity is the most serious problem of all because ratings are frequently used when a more objective measure cannot be developed. To the extent that rater errors exist and are not statistically adjusted out, the validity of the ratings is seriously contaminated.

Many strategies have been developed to reduce the impact of rater errors. These include training for raters, statistical adjustment for systematic differences between raters (e.g., leniency), and development of alternative evaluation strategies such as behaviorally anchored rating scales, ranking methods, forced choice, and the force distribution techniques.

L. Berger

RATING SCALES

In contrast to the items on a checklist, which require only a yes-no decision by the respondent, on rating scale items the respondent (rater) must make an evaluative judgment on some multicategory continuum. Introduced by Francis Galton in the nineteenth century, rating scales have been widely employed in business, industry, educational institutions, and other organizational contexts to evaluate various behavioral and personality characteristics. Such ratings are usually made by another person (e.g., a supervisor or peer), but individuals can also rate themselves.

Types of Rating Scales

On a numerical rating scale, the rater assigns to the person being rated (ratee) one of several numbers corresponding to particular descriptions of the characteristic being rated. A simple example of a numerical scale for rating a person on friendliness is to assign an integer from 0 to 4, depending on how friendly the person is perceived as being. Also illustrative of a numerical rating scale is the semantic differen-

tial technique, used extensively in studies of the connotative meanings of various concepts. Another widely used rating method is a graphic rating scale, in which the rater checks the point on the line corresponding to the appropriate description of the ratee.

On a standard rating scale, the rater supplies, or is supplied with, a set of standards against which ratees are to be compared. An example is the man-to-man rating scale, used for many years by the U.S. Army to rate officers on promotability. A man-to-man scale is constructed for rating individuals on a given trait, such as leadership ability, by having the rater think of five people who fall at different points along a hypothetical continuum of leadership ability. Then the rater compares each person to be rated with these five individuals and indicates which of them the ratee is most like in leadership ability.

On a forced-choice rating scale, raters are presented with two or more descriptions and are asked to indicate the one that best characterizes the ratee. If there are three or more descriptions, raters also may be told to indicate which description is least characteristic of the ratee.

Errors in Rating

An advantage of the forced-choice rating method is that it does a better job than other types of scales in controlling for certain errors in rating. Two errors are giving ratings that are higher than justified (leniency error) or lower than justified (severity error). Other errors are checking the average or middle category too often (central tendency error) and rating an individual highly on a certain characteristic or behavior simply because he or she rates highly in other areas (halo effect). Raters may also make the contrast error of rating a person higher than justified merely because a preceding ratee was very low or rating a person lower than justified because a preceding ratee was very high.

L. R. Aiken

RATIONAL EMOTIVE BEHAVIOR THERAPY

Rational emotive behavior therapy (REBT, formerly rational emotive therapy) is a theory of personality and a system of psychological treatment developed in the 1950s by Albert Ellis. It emphasizes the role of unrealistic expectations and irrational beliefs in human misery. The therapy's *A-B-C theory* of personality holds that emotions follow largely from cognitions and not from events. For example, should a family quarrel be followed by extreme anxiety, REBT asserts that emotional consequence C was not caused by activating event A but rather by some irrational belief or beliefs B about the nature or meaning of the quarrel, such as "I am an awful person" or "Without their approval, I cannot go on."

Ellis traces the origins of his insight about human upset back nearly 200 years to the writing of the later Stoic, Epictetus. In about C.E. second century, his disciple. Marcus Aurelius, emperor of Rome, wrote in his *Meditations,* "It is not this *thing* which disturbs you, but your own judgment about it. . . . Take away the opinion and there is taken away the complaint." REBT seeks to overcome disturbances caused by false beliefs and also to ameliorate the human predisposition toward crooked thinking that permits false beliefs to flourish. REBT theory considers emotional disturbance in the light of human nature in both its biological and social aspects.

Biological Origins of Personality

The lowest organisms may show complex, instinctive behavior in the apparent absence of learning. Such behaviors tend to be found in all members of a species and are performed in fixed stereotypical ways. For the most part, humans lack these fixed, universal behaviors, instead possessing a highly evolved capacity to acquire behaviors through learning and to retain them through habit. What is preprogrammed in humans is the clear predisposition to learn and form habits. Such predispositions make some sorts of things easier to learn than others. Children easily learn the desire to be loved rather than hated and readily prefer satisfaction of a want to its frustration. REBT stresses, however, that the predisposition to think is often the predisposition to think crookedly. The capacity to learn includes the capacity to learn nonsense. Among human predispositions with unfortunate consequences are tendencies to acquire desires for obviously hurtful things, to shed even grotesquely inappropriate habits only with great difficulty, and to think in terms of absolutes that distort even relatively accurate beliefs into disturbingly inaccurate ones.

Social Origins of Personality

Ellis found that many faulty cognitions appear throughout Western culture, such as beliefs that to have value one must be loved or approved of by virtually everyone and that it is a catastrophe when things go other than the way one wishes. Exaggerated, absolutistic beliefs establish impossible expectations. Thus, while people tend by nature to be happiest when their interpersonal relationships are best, most emotional disturbances result from caring too much about the opinions of others and from holding catastrophic expectations about the consequences of breached relationships.

Personality and Disturbance

REBT holds that because we are human, it is easy to learn to disturb ourselves and very hard to stop. Accordingly, REBT devotes considerable attention to the mechanisms by which disturbance is perpetuated. If thoughts are the

cause of emotional upsets, then thinking is the means by which disturbance is perpetuated: People disturb themselves and perpetuate their own misery through habitual internal verbalizations of irrational beliefs. Regardless of the origins of an irrational belief, it is maintained only by use. Eliminate the irrational thought and the upset dissipates. Eliminate the irrational thinking and the problem will not recur. People tend to be happier and more effective when they reduce their natural human tendency toward irrational self-reindoctrination and begin to think and behave more rationally.

REBT Approaches to Treatment

Although REBT therapists employ a wide variety of specific techniques in therapy, the intent is to minimize or eradicate irrational beliefs and to foster a more rational lifestyle. The therapist seeks to reeducate the client and to break down old patterns and establish new ones, using logic, reason, confrontation, exhortation teaching, prescription, role-playing, behavioral assignments and more. The central technique is disputation, a logicoempirical analysis through which irrational beliefs are identified and challenged.

Ellis has said that effective psychotherapy blends full tolerance of the client as an individual with a ruthless, hardheaded campaign against his self-defeating ideas, traits, and performances. The initial goal of therapy is to help the client achieve three insights. The first is that while self-defeating behaviors and emotional malfunctions have origins in the past and provocations in the present, their current and proximal cause lies with one's irrational beliefs, not with one's parents, history, or circumstances. The second insight is that these irrational, magical beliefs remain in force only because of the continued mixed-up thinking and foolish behaviors that reinforce them. People remain disturbed for only so long as they continue to reindoctrinate themselves. The third insight is that insights do not correct crooked thinking. Only hard work and practice can do this.

Fundamental to REBT is a broad campaign to push clients to work against their major irrational premises on several fronts. Humans can think rationally about their irrational thinking. REBT relies primarily on cognitive methods to show clients the flawed nature of their expectations, demands, and beliefs and to teach them to think more rationally. Emotive procedures, however, may also be used. Role-playing, for example, may elicit actual occurrences of irrational beliefs, upsets and behavioral tendencies, which can then be logically analyzed and corrected. Emotive methods are also employed to evoke feelings and reactions leading directly to changes in attitudes or values. As an active, directive, educative approach, REBT from the beginning used behavioral methods, both in the office and through homework assignments. Perfectionistic clients may be instructed to fail deliberately at some real task to observe the noncatastrophic nature of the consequences. Shy persons may be required to take progressively larger risks in social settings to learn that failure is neither inevitable nor intolerable.

Once clients begin to behave in ways that challenge their major behavioral beliefs, they are encouraged to continue to do so because actions may in fact speak louder than words in maintaining positive change. Ellis observed that people are rarely able to keep disbelieving their profoundly self-defeating beliefs unless they persistently act against them.

Depending on clinical needs, REBT often incorporates cognitive, emotive, and behavioral elements within a single case or single complex intervention. Regardless of the methods used, it remains constant: to help clients to foster what Ellis described as their natural human tendencies to gain more individuality, freedom of choice, and enjoyment and to help them discipline themselves against their natural human tendencies to be conforming, suggestible, and unenjoying.

READING DISABILITIES (ASSESSMENT)

Dyslexia is a common learning disability that affects the ease with which children learn to read and spell. Poor phoneme awareness is believed to make the major contribution to this difficulty learning to read and spell. Phoneme awareness refers to the ability to detect, manipulate, and order the individual sounds (phonemes) within words. Difficulty with this process makes learning the alphabetic code more difficult, leading to the reading and spelling difficulties that are the hallmark of dyslexia.

A good evaluation for dyslexia has several major components and taps several sources of information. These components include a careful history, quantitative test results, and a qualitative analysis of errors.

It is most efficient to obtain a developmental history questionnaire from parents prior to a meeting to review the child's history. Because there is a substantial genetic contribution to developmental dyslexia, a careful family history should be taken, which inquires about difficulties with reading, spelling, learning foreign languages, or other language difficulties in the child's parents and other close blood relatives. Early developmental histories of children with dyslexia are typically normal, although there may be some slight speech delay or articulation difficulties. The child with dyslexia typically shows some difficulty with

learning letter names and sounds in kindergarten, although there is considerable variability in this regard. In mildly affected or quite bright children who are educationally advantaged, there may be little concern about progress in kindergarten. Other children show striking difficulties with learning the alphabet in spite of much extra help. Difficulty with learning to read and spell is typically noted in the early grades. Parents should be carefully queried about the child's spontaneous spelling because many children with dyslexia are able to learn words for a spelling test only to forget them very quickly and thus are occasionally not described as poor spellers early on. Difficulty with learning the multiplication tables is a very common problem and is related to difficulties with rote verbal memory that are typically seen in children with dyslexia. For older children, there are often concerns about poor spelling and slow, effortful reading, which often leads to poorer performance on timed tests. Finally, learning a foreign language is typically difficult.

Following the gathering of history, testing is conducted with the child. A typical assessment battery might take approximately 3 to 4 hours or even more, depending on whether there are other related questions. A description of specific tests in a sample battery follows, but other tests that assess the same functions and skills could be substituted. The important issue is that the various functions and skills described be evaluated.

The first major area that should be assessed is general intellectual ability, for which the Wechsler Intelligence Scale for Children–III (WISC-III) is one recommended instrument. Dyslexia cannot be diagnosed based on WISC-III scores, but there are some score patterns and some qualitative observations that can be helpful. Specifically, scores are often somewhat weaker on the Arithmetic and Digit Span subtests, which both require verbal working memory among other capacities. On the Performance scale, the Coding subtest, which requires learning a new symbolic code and good visuomotor skill, is often somewhat weak. Qualitatively, word-finding difficulties are often evident on the Picture Completion subtest as the child may correctly locate the missing element in the picture but be unable to provide the name quickly. Likewise, on the Information subtest, it is not uncommon for the child to make errors on relatively easier items where specific names of people or months are required, even though more difficult items that are more conceptual are subsequently passed.

After general intellectual ability, another major function to be assessed is phonological processing. The Comprehensive Test of Phonological Processing (CTOPP) is one useful test battery for this purpose. The Woodcock-Johnson III also has a useful Sound Awareness subtest. The Lindamood Test of Auditory Conceptualization is another useful test in this category. All of these tests tap the child's ability to isolate and manipulate phonemes within words. Weakness in this area is a core underlying deficit in dyslexia. The CTOPP additionally has a Rapid Naming Cluster, which taps lexical retrieval by having the child rapidly name letters and numbers.

Another area that needs careful assessment is the child's skill levels in reading and written language and preferably also in math. The Woodcock-Johnson III Psychoeducational Battery has subtests covering the necessary areas, but other batteries are also certainly appropriate. It is important to test the child's single-word reading, nonsense-word reading (Word Attack), spelling, and calculation skill.

In addition to testing single-word and nonsense-word reading, it is also important to test contextual reading in a way that takes time into account. It is not unusual for a child with dyslexia to obtain a score close to grade level on an untimed test of reading; their genuine deficit may not become readily apparent until the rate and accuracy of their reading are taken into account. The Gray Oral Reading Test–4 is a good instrument for assessing reading in this way because it provides scores for reading rate, accuracy, and comprehension. Another test that taps reading rate is the Test of Word Reading Efficiency, in which the child reads lists of sight words and nonsense words in a specified time, and the score is based on the number of words which the child is able to read. In addition to the quantitative scores on these reading tests, a qualitative analysis of errors should be made, which can be helpful in guiding remedial efforts. In assessing spelling, it is important that a dictation-type test (rather than multiple choice) be used so that a qualitative analysis of the types of spelling errors can also be made. Children with dyslexia are particularly prone to dysphonetic errors (errors that indicate poor tracking of the sound sequence in the word). This kind of qualitative analysis is also useful in guiding remedial efforts.

The evaluation should conclude with a feedback conference with parents at which results are carefully explained and recommendations made. Because the most important goal of an assessment for dyslexia is to provide guidance about appropriate interventions, the information from the evaluation should be summarized in a written report. Interventions can be thought of in terms of two broad categories: remediation and compensation. Remediation refers to direct teaching to improve the child's weak skills, and there are numerous effective programs for this purpose. These share a focus on the child's poor phoneme awareness and mastery of the alphabetic code in highly structured and programmatic ways. A good remedial program also includes considerable practice in contextual reading, using techniques such as guided oral repetitive reading to address the difficulties children with dyslexia have with achieving silent reading. Compensation refers to various procedures that teachers and others can use in order to facilitate the child's learning and guard self-esteem while remedial efforts are being undertaken. Like remediation, these must be geared to the individual needs of the child and include, for example, more time on tests, some relaxation of spelling requirements on in-class work, caution in asking younger poor readers to read aloud in class, and various methods of

assisting with the difficulty with math fact memorization that can interfere with the child's math progress.

Finally, it should be emphasized that the knowledgeable assessment of dyslexia is particularly important because so much can be done to help the child with dyslexia when this condition is correctly identified and remediated.

RECIPROCAL INHIBITION

Central nervous systems (CNSs) together with peripheral reflex loops form the basis of all animal movements. It has long been recognized that the CNS is primarily responsible for generating the motor-neuron firing patterns that underlie repetitive movements—that is, those that have a rhythmic expression (Delcomyn, 1980). An important aim in neurobiology is to identify the neuronal circuits underlying these rhythmic behaviors and to understand how the rhythmic motor patterns arise from neuronal connections and neuronal properties (Friesen & Stent, 1978).

The term *reciprocal inhibition* refers to a model or concept that was formulated at the beginning of the previous century by Brown (1911) to explain the neuronal origins of rhythmic walking movements. This first explanation for how a circuit of neurons can cause alternating limb movements was formulated long before specific neuronal circuits were identified. At that time, experiments by several researchers, including Brown, demonstrated that the stepping movements of animal limbs could be elicited even in deafferented mammalian preparations. That is, cats that had sensory axons severed to remove all possibility of sensory feedback from the periphery to the CNS could still perform at least the rudiments of stepping movements. These experiments led to the concept that a CNS oscillator exists within the vertebrate spinal cord to generate the neuronal impulse patterns that lead to repetitive animal movements. Brown's model for this central spinal oscillator envisioned two sets of neurons coupled by reciprocal (i.e., mutually) inhibitory synapses (Figure 1, panel A) for each limb or even for each joint. Because of the synaptic inhibitory connections, only one of the two inhibitory neurons (or perhaps pools of inhibitory neurons) can be active at any one time. Moreover, the activity of the two neurons alternates (Figure 1, panel B). With appropriate connections to motor neurons, output of these inhibitory neurons can control the activity of first flexor and then extensor motor neurons. Thus, the alternating neuronal patterns generated by the central circuit can drive the appropriate impulse patterns needed to command rhythmic flexion and extension, and hence to forward and backward movements of individual limbs (Brown, 1911).

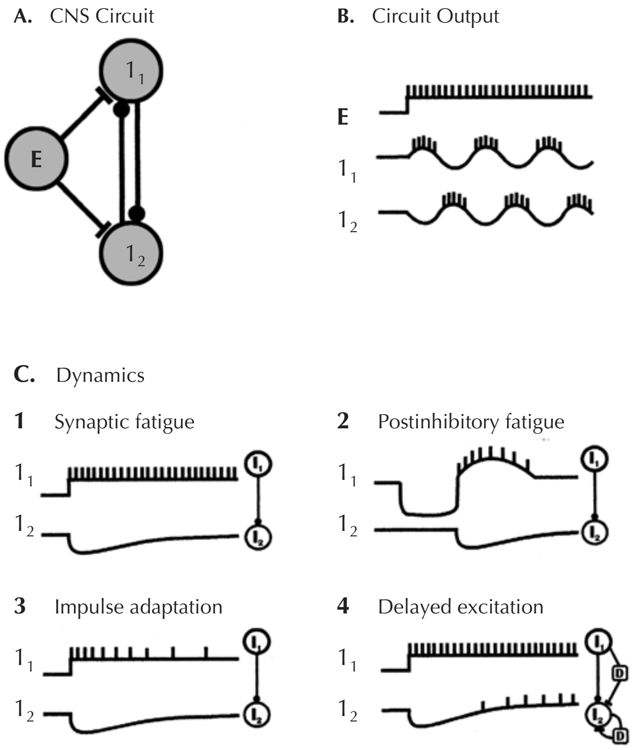

Figure 1. Model of reciprocal inhibition. A. *Circuit diagram.* Three neurons, one excitatory (E) and two inhibitory (I_1 and I_2) are interconnected by excitatory (—|) and inhibitory (—o) synapses. The output of this circuit (B.) consists of antiphasic membrane potential oscillations and impulse bursts generated by the two inhibitory neurons when the excitatory cell is active. C. *Dynamic properties important for reciprocal inhibition.* Insets to the right illustrate synaptic interactions. Upper traces in each part show the activity of presynaptic neurons; lower traces illustrate the effects on postsynaptic cells. C1. *Synaptic fatigue.* Excitatory drive to I_1 generates an initially large, then declining, hyperpolarization in I_2. C2. *Postinhibitory rebound.* When neuron I_1 is hyperpolarized briefly, the termination of the inhibition is followed by an excitatory response whereby the membrane potential overshoots rest to generate a burst of impulses. This PIR causes transient inhibition in neuron I_2. C3. *Impulse adaptation.* Excitatory drive to neuron I_1 elicits a train of impulses whose frequency declines with time. The effect on neuron I_2 is hyperpolarization, whose amplitude gradually decreases. C4. *Delayed excitation.* D designates delayed onset of excitation, which might either be synaptic or cellular.

Simple reciprocal inhibition alone cannot generate oscillations. Rather, additional dynamic (time-varying) properties are needed to ensure that mutually inhibitory neurons do not act as a simple, bistable switch (Friesen & Stent, 1978). Brown (1911) proposed two such dynamic properties: synaptic fatigue, a synaptic property; and postinhibitory rebound (PIR), a cellular property. If the strength of synaptic interactions is labile in a reciprocally inhibitory circuit, continuous excitation of either neuron will only transiently inhibit the other one (Figure 1, panel C1). If both neurons of the reciprocally inhibitory pair receive continuous excitatory input, the result will be antiphasic oscillations, as demonstrated by the following consideration. If neuron 1 is

activated first, it will inhibit neuron 2 until the synapse fatigues. Once the synapse has weakened, neuron 2 will be relieved of inhibition and will be activated by the excitatory input, shutting off neuron 1. While neuron 2 is active, the synaptic terminal of the inhibited neuron recovers from fatigue and can once again inhibit neuron 2 when the synapse from neuron 2 to neuron 1 has weakened sufficiently for neuron 1 to become reactivated.

In neurons expressing the dynamic property PIR, the membrane potential overshoots the resting level at the termination of an inhibitory, hyperpolarizing input (Figure 1, panel C2). Also termed *paradoxical excitation,* this property provides transient excitatory drive when inhibition ceases. Membrane properties that can generate PIR include inactivation of a sodium conductance, such as is associated with the nerve impulse, and activation of an excitatory, inward current by membrane hyperpolarization (Calabrese & Arbas, 1989). As Brown (1911) realized, postinhibitory rebound in a circuit consisting of two reciprocally inhibitory neurons can suffice to generate stable, antiphasic oscillations (Perkel & Mulloney, 1974).

Two additional dynamic properties that can contribute to rhythmicity in neuronal circuits have been proposed. One cellular property is impulse adaptation, in which a continuously excited neuron emits a train of impulses with decreasing frequency (Figure 1, panel C3). The effect of adaptation, like that of synaptic fatigue, is to limit the duration of inhibition, again ensuring that a pair of mutually inhibitory neurons alternates activity, rather than forming a bistable switch. A final dynamic effect is delayed excitation, which can arise either because of complex circuit properties in which the inhibitory interaction between cells is superceded in time by synaptic excitation or because of hyperpolarization-induced excitatory currents. Rather than reducing the amplitude of the inhibitory interaction, these two cellular and circuit properties act as sources of delayed excitatory drive to overcome synaptic inhibition (Figure 1, panel C4).

Brown's (1911) neuronal model for rhythm generation is known either as reciprocal inhibition or as the half-center model. Although reciprocal inhibition served as the only important conceptual model for generating rhythmic movements for many years, it was first authenticated experimentally by the finding that reciprocal inhibition is one component of the rhythm-generating mechanism in the pyloric system of the lobster stomatogastric ganglion (Miller & Selverston, 1985). Since then, the model has been applied with success to a variety of neuronal circuits that generate animal behavior (Friesen, 1994). Examples include swimming movements in lamprey, tadpoles, the marine mollusks *Clione* and *Tritonia,* and the leech. The rhythmic contraction of leech heart tubes provides an especially well-described preparation in which reciprocal inhibition generates the oscillations (Calabrese & Arbas, 1989).

REFLECTIVE LISTENING

Reflective listening is a way to communicate empathy, an important element of psychotherapeutic interaction. Carl Rogers wrote that

> being empathic has several facets. It means entering the private perceptual world of the other and becoming thoroughly at home in it. It involves being sensitive, moment to moment, to the changing felt meanings which flow in this other person, to the fear or rage or tenderness or confusion or whatever, that he/she is experiencing. It means temporarily living in his/her life, moving about in it delicately without making judgments, sensing meanings of which he/she is scarcely aware, but not trying to uncover feelings, since this would be too threatening. It includes communicating your sensings of his/her world as you look with fresh and unfrightened eyes at elements of which the individual is fearful. It means frequently checking as to the accuracy of your sensings, and being guided by the responses you receive. You are a confident companion. By pointing to the possible meanings in the flow of his/her experiencing you help the person to focus on this useful type of referent, to experience the meanings more fully, and to move forward in the experiencing.
>
> To be with another in this way means that for the time being you lay aside the views and values you hold for yourself in order to enter another's world without prejudice. In some sense it means that you lay aside your self and this can only be done by a person who is secure enough [to] not get lost in what may turn

> out to be the strange or bizarre world of the other, and [to] comfortably return to his own world when he wishes. (Rogers, 1975)

The importance of empathic listening has been written about in many approaches to psychotherapy including client-centered, self psychology, psychoanalysis, Gestalt, existential, focusing-oriented, pretherapy, child therapy, marital and couple therapy, disaster-recovery therapy, and clinical supervision. Some emphasize the importance of nonverbal components of empathy. Empathy shares aspects of mental discipline with meditation. Empathic ability is not strongly associated with academic or diagnostic proficiency.

Reflective listening involves holding a distinct set of attitudes toward the person being listened to. There is an acceptance of the content of the person's awareness. The listener trusts the resources of the speaker to evaluate, analyze, and decide and therefore does not give advice and suggestions about what to do or how to perceive. When listening, one is nondiagnostic and nonevaluative.

Communicating one's empathy is often best accomplished by using much the same language as the person in order to avoid possible connotations of different language that would not be correct for the speaker. This does not mean limiting oneself to literally what was said. The listener senses for and reflects meanings not yet clear, some not yet mentioned in words, that have been expressed nonverbally. Frequently communicating one's empathy, as often as a couple of times per minute to stay in close contact, gives the speaker ample opportunities to correct misunderstandings or to revise what he or she says to articulate experiencing as it evolves.

Listening has useful effects: In the process of being accurately and caringly understood, feelings and ideas change in problem-solving, insight-producing, tension-releasing, responsibility-building, and conflict-reducing ways. In addition, the person gets the message that his or her experience makes sense and that he or she is worthy of being taken seriously.

Paradoxically, this powerful way to foster change involves the listener's studiously not pushing for change. The listener accepts what the speaker says on the speaker's terms, without dispute.

Eugene Gendlin (1981, 1996) clarified the *object* to which the listener listens. The *bodily felt sense* is more inclusive than what one is clearly aware of consciously, including everything felt at the moment, even if only vaguely and subliminally. It often has opposing impulses in it. It is not a static object but changes from moment to moment as events proceed. It is this fluid object that the listener reflects.

Through research, Gendlin, Rogers, and others came to believe that certain attitudes, when directed toward the bodily felt sense, resulted in more positive personality change than did other attitudes. These attitudes include patience, gentleness, warmth, interest, respect, curiosity, and an expectation that something new can be discovered. This is in contrast to attitudes of criticism, control, evaluation, or neglect.

Listening creates an interactional opportunity for the speaker to experience and have supported his or her own capacities for solving problems, for identifying the part he or she contributes to interpersonal difficulties, for building self-esteem, and for sorting out complicated personal concerns and motives. The common helper attitudes of evaluation, diagnosis, analysis, and advice seem to have the opposite effect: that of stopping this kind of process in favor of an attitude of dependence on (or resistance to) the guidance of external authority.

Reflecting is a limited metaphor for empathic listening. It does not adequately convey the change produced by good listening, nor the way in which it is an intimate relationship event. The speaker experiences the calming, enlightening embrace of an affectionately indifferent, accepting attitude democratically encompassing all presently experienced emotions, thoughts, sensations, and images. This embrace, provided by the listener, enables the speaker to move toward unconditional acceptance and understanding of his or her subtle and complex experiencing. Ann Cornell (1994) refers to this intrapersonal attitude as the "radical acceptance of everything." It has a remarkable power to release one's energy to move forward in constructive ways.

Reflective listening is valued beyond psychotherapy. Thomas Gordon recommends it to parents as a means of maintaining open and trusting relationships with their children and to health care professionals for improving relations with patients. Teachers who are rated more empathic have been shown to achieve greater student involvement in educational settings. Empathic listening has also been found helpful for school administrations in dealing with parents. It plays a role in improving intimacy in spousal relationships. Clinical and vocational supervision situations also benefit from this skill. Many conflict management and mediation approaches use reflective listening as a core technique. Writings about building community emphasize the value of empathic listening techniques. Some philosophical writings also cite this form of communication as a beneficial dialectical method.

Kenneth Clark (1980) believed that empathy utilizes the most recently evolved part of the brain and that it counterbalances egocentric power drives. Thus, reflective listening may have great social significance toward collective solutions to resource allocation and peaceful human relations.

REFLEXES

A reflex is the central nervous system's least complex, shortest-latency motor response to sensory input. The expression of a reflex is an involuntary, stereotyped contraction of muscles determined by the locus and nature of the eliciting stimulus. Reflexes may be elicited by stimulation of any sensory modality. There are many reflexes; an exhaustive listing is not provided here. Rather, the principles that apply to all reflexes are described using a few examples.

The simplest reflex is the myotatic, or muscle stretch, reflex. This reflex can be elicited from any skeletal muscle, but the best known example is the patellar, or knee-jerk, reflex. The anatomical basis of the myotactic reflex is the monosynaptic (one synapse) connection between the sensory fibers that detect stretch on a muscle and the alpha (tr) motor neurons that supply nerve fibers to that same muscle. The sensory fibers have their cell bodies in the dorsal root ganglia. One end of the sensory fiber terminates in the sensory end-organ for muscle stretch, known as the muscle spindle. The other end of the nerve fiber enters the spinal cord through the dorsal root and dorsal horn and terminates in the ventral horn of the spinal cord on an a motor neuron.

Muscle spindles are embedded in the mass of each striated muscle. They are arranged in parallel with the extrafusal muscle fibers that contract when the motor nerves supplying them are stimulated. The central portion of the spindle is nonmuscular and receives the sensory nerve ending. When the central portion of the spindle is stretched, the sensory nerve increases its rate of production of action potentials. The axons that provide the input for the stretch reflex are the largest of the sensory nerve fibers and are called type Ia. Conduction is very rapid in these nerves. This fact, and the fact that they each make a monosynaptic contact with a motor neuron supplying the extrafusal muscle fibers, ensures that the reflex contraction of the whole muscle in response to stretch is very rapid. When the muscle contracts, the muscle spindle shortens; the stimulus for sensory discharge is reduced, and the rate of action potential production in the sensory fibers decreases or stops.

In addition to a nonmuscular sensory middle, the muscle spindle has muscular tissue attached to each of its ends. These muscular endings of the muscle spindle are called intrafusal muscles and do not contribute to the contractile strength of the muscle. They are innervated by their own type of motor neuron called the gamma (γ) motor neuron. Motor areas in the brain, particularly in the reticular formation, send axons that influence the γ motor neurons and through this connection can modulate the stretch reflex by changing the tension on the nonmuscular central portion of the spindle.

The stretch reflex demonstrates the basic principles of all reflexes. A sensory, or afferent, limb is necessary. Severing the dorsal roots eliminates the stretch reflex. The eliciting stimulus is specific. The reflex is produced by stretch on the muscle, not by touch, pain, or some other stimulus. A motor, or efferent, limb is necessary. Severing the ventral roots eliminates the reflex. The efferent response is specific. Only the muscles that are stretched will reflexively contract. The reflex is graded. The greater the stretch, the greater the contraction.

More complex reflex arcs also exist. The anatomy of these reflexes includes the interposition of one or more interneurons between the afferent and efferent limbs of the reflex. These reflexes, therefore, have more than one synapse and are called polysynaptic. The Golgi tendon organ reflex provides an example of the simplest polysynaptic reflex. The sensory end-organ is found in the tendon; its cell body is in a dorsal root ganglion. Increased tension on the tendon, usually produced by contraction of the muscle to which it is attached, is the eliciting stimulus that increases activity in the tendon organ afferent fiber. The tendon organ afferent fiber synapses on an interneuron in the spinal cord. This interneuron inhibits as a motor neuron, thus decreasing activity in its efferent axon. Because this axon returns to the muscle to which the stretched tendon is attached, the muscle relaxes and the tension on the tendon is reduced.

The muscle stretch reflex and the Golgi tendon organ reflex work in concert to provide the basis for rapid regulation of the degree of contraction of the muscle. For example, these reflexes are useful for quick adjustments to change the position of the foot as a person hikes across uneven ground.

Other polysynaptic reflexes are involved in movement of whole limbs and the coordination of different limbs. These reflexes incorporate more interneurons. The divergent (from one neuron to several neurons) and convergent (from several neurons to one neuron) connections of the interneurons form the basis of these complex reflexes. An example is provided by a person who steps barefooted on a sharp object and reflexively withdraws the injured foot. The sensory input is pain. The pain afferents enter the dorsal horn of the spinal cord and continue to its ventral division, where they synapse on interneurons. Some of these interneurons excite motor neurons that cause the flexor muscles of the affected leg to contract to lift the foot, while other interneurons serve to inhibit the motor neurons that supply the extensor muscles of the same leg. This permits the leg to withdraw quickly and smoothly from the noxious stimulus.

Other neurons receiving pain input send axons across the midline of the spinal cord and excite the motor neurons for extensors of the opposite leg and inhibit those that innervate that leg's flexors. This causes the leg to stiffen and provide support. Furthermore, interneurons relay information up and down the spinal cord to produce intersegmental reflexes that coordinate muscle contraction of the trunk and upper limbs. The entire reflex is known as the flexion–crossed extension reflex.

The spinal cord reflexes form the basis for maintenance and adjustment of posture. Brain motor systems influence spinal cord reflexes via input to interneurons and the γ motor neurons to produce normal movement and modulate reflexes. Changes in spinal cord reflexes may indicate pathology in the brain motor systems. For example, damage to the motor cortex or to axons originating in this part of the brain produces increased reflex response to muscle stretch.

Several optic reflexes exist. An example is the direct light reflex, which is the constriction of the pupil to light. It requires an intact retina, optic nerve, midbrain, and third cranial nerve, but not the lateral geniculate nucleus or visual cortex. If light is restricted to one eye only, a crossing pathway at the pretectal level of the mid-brain produces constriction of the pupil opposite to the one into which the light is introduced; this is called the consensual light reflex. Several reflex changes (accommodation reflex) also occur when the eyes are directed toward a near object. These include convergence of the eyes as the medial recti contract, thickening of the lens, and pupillary constriction. Many components of the visual system are involved in this reflex, including the retina, optic nerve, occipital cortex, superior colliculus, lateral geniculate nucleus, and nuclei of the oculomotor nerve.

Reflexes can also be elicited from stimulation of sensory input from the viscera. The baroreceptor reflex is an example of such an autonomic reflex. An increase in blood pressure stretches receptors in large vessels near the heart. This increases afferent input to nucleus tractus solitarius of the medulla. Neurons in the nucleus tractus solitarius relay activity to the motor nucleus of the vagal nerve, as well as to the spinal cord autonomic neurons, and heart rate and blood pressure decrease.

REHABILITATION PSYCHOLOGY

Rehabilitation psychology is a specialty area of practice within the broad field of psychology. Rehabilitation psychology is the application of psychological knowledge and understanding on behalf of individuals with disabilities and society through such activities as research, clinical practice, teaching, public education, development of social policy, and advocacy. Professionals who provide rehabilitation psychology services are called rehabilitation psychologists. Rehabilitation psychologists participate in a broad range of activities including clinical care, program development, service provision, research, education, administration, and public policy.

Rehabilitation psychologists work in diverse settings including acute care hospitals and medical centers, inpatient and outpatient physical rehabilitation units/centers, nursing homes and assisted living centers, community agencies specializing in services for a particular type of disability (e.g., cerebral palsy, multiple sclerosis, deafness), and other types of settings such as pain and sports injury centers and cardiac rehabilitation facilities. They may work for private facilities or for such government facilities as Veterans Administration hospitals and centers. Rehabilitation psychologists serve individuals throughout the life span, from early childhood through late adulthood. Many rehabilitation psychologists are full-time university or college faculty and focus primarily on teaching and research. Others may work in or consult industry, provide expert legal testimony, or conduct assessments and evaluations for insurance agencies. Rehabilitation psychologists advocate for improvement of life conditions for people with disabilities; as such they are involved in the development and promotion of legislation such as the Americans with Disabilities Act.

Rehabilitation psychologists who provide clinical and counseling services assist individuals in coping with, and adjusting to, chronic, traumatic, or congenital injuries or illnesses that may result in a wide variety of physical, sensory, neurocognitive, emotional, and developmental disabilities. These may include (but are not limited to): spinal cord injury; brain injury; stroke; amputations; neuromuscular disorders; medical conditions with the potential to

limit functioning and participation in life activities such as cancer, AIDS, multiple sclerosis, or limb weakness; chronic pain; congenital or chronic developmental disorder such as mental retardation; severe psychiatric disability; substance abuse; burns and disfigurement; deafness and hearing loss; blindness and vision loss; and other physical, mental, and emotional impairments compounded by cultural, educational, or other disadvantages.

Rehabilitation psychologists provide services with the goal of increasing function and reducing disability, activity limitations, and restrictions on societal participation. The person served is seen as an active partner in the treatment process, and, thus, the services provided take into account the person's preferences, needs, and resources. Consistent with the World Health Organization's recently adopted International Classification of Functioning, Disability, and Health (ICF), the rehabilitation psychologist works with the individual with a disability to address personal factors impacting on the ICF domains of activities and participation. This includes assessing and addressing neurocognitive status, mood and emotions, desired level of independence and interdependence, mobility and freedom of movement, self-esteem and self-determination, and subjective view of capabilities and quality of life as well as satisfaction with achievements in specific areas such as work, social relationships, and being able to go where one wishes beyond the mere physical capability to do so. Rehabilitation psychologists take the influences of culture, ethnicity, gender, residence and geographic location, relative visibility, and assumption of disability on attitudes and available services into account when planning services and interventions. Rehabilitation psychologists explore with individuals environmental barriers to their participation and activity performance and the means to address these barriers including accommodations and adaptations in existing structures or materials, the use of assistive technology, and the use of personal assistance services. For individuals with severe disabilities or chronic illnesses, a blend of these products and services is often most beneficial.

The rehabilitation psychologist provides services to families and primary caregivers as well as other significant people in the individual's social-community circle (e.g., teachers, employers, clergy, friends). The goal of rehabilitation psychology is to assist the individual (and those significant others who are involved in treatment planning and ongoing provision of support) in achieving optimal physical, psychological, and interpersonal functioning by addressing the obstacles preventing the highest level of personal and social functioning. Rehabilitation psychologists view persons served holistically, and they seek to broaden opportunities for maximum individual functioning as well as functioning and participation in social relationships, social activities, education, employment, and the community.

Some rehabilitation psychologists work within a broad variety of health care settings and with a broad range of persons with varying disabilities, whereas others specialize in a particular area of clinical practice. Regardless of setting or area of specialization, the rehabilitation psychologist is consistently involved in interdisciplinary teamwork and provides services within the network of biological, psychological, social, environmental, and political environments to assist the persons served in achieving desired rehabilitation goals. Thus, in addition to working directly with the persons served and their families, rehabilitation psychologists often serve an important role in providing consultations regarding disability and health issues to attorneys, courts, government agencies, educational institutions, corporate facilities, and insurance companies.

Rehabilitation psychologists have completed doctoral degrees in psychology and have had extensive predoctoral and postdoctoral training in health care settings. Further, rehabilitation psychologists providing clinical services are usually required to be licensed in order to provide services in their state of practice and to receive reimbursement for services from health insurance payers. The American Board of Professional Psychology (ABPP) recognizes rehabilitation psychology as a specialty area of practice within psychology. The ABPP's definition of rehabilitation psychology was a significant and primary source in the development of the present description.

Although rehabilitation psychologists belong to many professional organizations relevant to their area of practice and specialization, the major organization representing rehabilitation psychology is the American Psychological Association, Division of Rehabilitation Psychology (http://www.apa.org/divisions/div22/). This division publishes a scholarly journal and newsletter and sponsors sessions relevant to rehabilitation psychology research and practice at the annual APA conference as well as other education venues for psychologists and other health professionals.

The American Psychological Association can be contacted for a list of rehabilitation psychologists in the United States as well as those members who live outside the United States. Finally, there are excellent textbooks available on the general topic of rehabilitation psychology as well as books on areas of specialization within this field.

REINFORCEMENT

Thorndike's statement of the law of effect reads as follows:

> The law of effect is that: Of several responses made to the same situation, those which are accompanied or closely followed by satisfaction to the animal will, other things being equal, be more firmly connected to the situation, so that, when it recurs, they will be more likely to recur; those which are accompanied or closely followed by discomfort [annoyance] to the animal will, other things being equal, have their connections to that situation weakened, so that, when it recurs, they will be less likely to occur. The greater the satisfaction or discomfort, the greater the strengthening or weakening of this bond.

With the development of reinforcement theory, chiefly at the hands of Clark L. Hull, the key terms in the law of effect, *satisfaction* and *discomfort,* became positive and negative reinforcement. Positive and negative reinforcement are theoretical concepts just as Thorndike's satisfaction and discomfort were. These effects are created by the manipulation of more objective conditions, positive reinforcers (rewards and satisfiers in Thorndike's terms) and negative reinforcers (punishers and annoyers in Thorndike's terms). Whether the effect is positive or negative, reinforcement depends on whether the positive or negative reinforcer is delivered or withheld. Positive reinforcement may be produced either by the presentation of a reward or by withholding a punishment when a particular response occurs; negative reinforcement may be produced either by the presentation of a punisher or by withholding a reward when a particular response occurs. These four arrangements define a basic classification of types of operant conditioning: (1) *reward training*—food is delivered when the rat presses the lever in the Skinner box; (2) *active avoidance training*—the rat avoids electric shock by crossing to the opposite side of a shuttle box; (3) *passive avoidance training*—the rat receives electric shock if it steps down from a platform onto a grid; (4) *omission training*—the rat receives food only if it fails to press the bar in the Skinner box.

REINFORCEMENT SCHEDULES

In operant conditioning theory, a behavior is maintained by its consequences, that is, by the reinforcing or punishing events that follow the behavior. The relationship between a behavior and its consequences is called a contingency. Reinforcement generally operates on an intermittent schedule of some sort. Skinner pointed out that reinforcement may be scheduled in many ways and demonstrated that subtle differences in scheduling can generate dramatic differences in behavior.

Four basic schedules of reinforcement have been studied in detail. Two are ratio schedules, in which the presentation of a reinforcer is contingent on the number of responses emitted by the organism. In a fixed ratio (FR) schedule, every nth response is reinforced. In a variable schedule (VR), responses are reinforced on a certain average ratio, but the number of responses required for reinforcement varies unpredictably from reinforcement to reinforcement. The other two basic schedules are interval schedules, which are defined by the length of time that must elapse between reinforcements. The first response to occur after this time has elapsed is reinforced. In fixed interval (FI) schedules, this interval remains constant from reinforcement to reinforcement; in variable interval (VI) schedules, the intervals between reinforcements vary randomly about some mean interval.

In addition to these four basic schedules, there are a number of other schedules, such as differential reinforcement of low rates of response (DLR), differential reinforcement of other behaviors (DRO), and various complex and concurrent schedules, which are combinations of the four basic schedules.

Each schedule has a particular effect on behavior. Ratio schedules generally produce high rates of response, and interval schedules produce lower rates of response. Variable schedules, particularly variable interval schedules, produce a remarkably stable pattern of behavior. Behaviors maintained under variable schedules are also highly resistant to extinction. This fact helps to explain why it is so difficult to extinguish undesirable behaviors, since most behaviors are maintained under variable schedules.

RELATIONSHIP THERAPY

Relationship therapy refers to several forms of psychotherapy that invoke the relationship between the therapist and client as the effective change mechanism. In contrast, insight and behavior change are the mechanisms of change for psychoanalysis and behavior modification, respectively. Additionally, the term *relationship therapy* has come to refer to treating relationships as the focus of therapy.

The Relationship as the Mechanism of Change

Two central theorists of relationship therapy are Martin Buber (1974) and Harry Stack Sullivan (1953), although

Carl Rogers (1951) and Eric Berne (1964) played important roles in the development of the theory and practice of relationship therapy.

Buber saw the essence of human living as the encounter in a direct experience between one person and another (I-Thou), rather than as the act of one person's seeing another (and being seen) as an object or through the barriers and filters of social roles (I-It). The humanizing influence of one person's I-Thou experiencing on the other allows the other to feel fully human. Buber saw people not as static diagnostic entities such as neurotics or schizophrenics to be treated (which would be I-It relationships) but as humans in need of a direct I-Thou relationship with another human. Thus the therapist, who is the expert in human relationships, provides a chance for the person to encounter another in dialogue or the I-Thou experience. This experience is the curative element and, in its more general form, is both the prophylactic and antidote to the oppression of a mechanistic and increasingly bureaucratic society that makes people into *its* rather than *thous.* Buber's influence catapulted with the 1922 publication of *I and Thou* (1958), reached a peak in the 1950s and 1960s, and remains a force in pastoral and humanistic counseling today.

For Sullivan, personality develops as a function of the relationship. For example, an infant born to a teenage mother who consequently could not go to college would be viewed by that mother differently than would a baby who was born to a long-childless couple who desired a baby. The parents' reactions constitute appraisal that is reflected back to the developing person either overtly, by verbal and other behavior, or covertly, by facial and emotional expression and by vocal tone. The developing self contributes to personality or, to use Sullivan's term, the *envelope of energy transformation.* Abnormal behavior is the stereotyped response, or *parataxic distortion,* to others for whom the response is not fitting. The psychotherapist begins the four stages for treatment with the inception or initial sizing-up of the patient and of one another and processes to the reconnaissance, which is the more formal history taking of the patient. The therapist is ever mindful of the emotional tone from moment to moment in each session and for each topic. The problematic areas are scrutinized during the detained inquiry, and progress is summarized in the termination phase. Anxieties or insecurities are revealed during the examination of the patient's life, although various warps or strains in the relationship are seen in slips of the tongue, stuttering, misused words, and gestures inconsistent with verbal statements or with the mood of the moment. The therapist might sense these moods of the moment via Sullivan's reciprocal emotions or through the strains or pulls produced by the patient during the session. This sensing of the other may result in the therapist's responding in a way that the patient can use to examine his or her experience. The therapeutic and unusual response may allow the patient to unhook, or behave in a new way because their old behaviors did not bring about the usual and desired response from the therapist. The therapist provides a noncondemning environment for such experimenting. Sullivan's influence is strong but not generally acknowledged currently.

Rogers saw humans as motivated to grow when provided with the right conditions. These conditions could be supplied within the counseling or therapeutic context when the right relationship was presented. The basic ingredients include the theorist's unconditional positive regard, empathic understanding, and congruence of feelings that were communicated to the patient in the therapeutic relationship. Berne saw games or enactments of the scripts we learn early in life within relationships in which people assume one-up and one-down roles. Thus one person might play parent or caretaker to another person's child or help-seeking role.

Contemporary Developments

Relationship as the Therapeutic Modality

Recently, the traditional metaphors from the several dominant theoretical perspectives have grown brittle with age. The theoretical approaches have gravitated toward realizing the role of the relationship as the force accounting for effectiveness in psychotherapy. Psychoanalytic approaches have developed the idea of intersubjectivity as a way of including the role of the relationship between the psychoanalyst and the analysand as the change mechanism in therapy. Intersubjectivity denotes the interpersonal transactions in psychotherapy and the way by which corrective emotional experiences transpire. The corrective emotional experience might occur when the therapist responds in a different and asocial fashion to a set of patient behaviors that previously elicited a particular and stereotyped response. Thus, a sexually seductive or coy behavior by a patient that does not elicit a sexual advance from the therapist provides the patient with the opportunity to experience him- or herself differently. The patient might now have to examine why he or she might be stuck in the role of using him- or herself as a sexual object in order to interact with others.

Behavioral approaches recognize relationship factors by increasingly employing such notions as nonspecific therapist factors and the role of context in behavior change. This contrasts with the more traditional use of behavioral reinforcement as the central and sole source of change in effective behavioral therapy. The role of the therapist's personality in structuring the relationship and the use of the theorist-in-relationship are more realistic approaches to how behavior change works. The shift in behavioral theory and practice accords well with the therapy effectiveness research. Such research has found that the curative aspects of psychotherapy center on the nature of the relationship and the working through of patient problems.

Treating the Relationship

Traditional Sullivanian thinking has developed into systems theory. Variants of systems theory focus on treating the relationship. The family therapy theories developed by Bowen (1978), Haley (1963), Madanes (1981), Minuchin (1974), and Satir (1967, 1972) are prime examples of relationship therapies. Another group of therapists who focused on relationships concern themselves with conducting marital therapy. John Mordechai Gottman (1995) has been foremost in his research and treatment program for defining marital troubles and their treatment. Relationship treatments tend to be time limited; active in interventions; problem focused; present oriented; interpersonal; and oriented to coping, identifying assets, and improving relationships.

RELIABILITY

The reliability of a test refers to its consistency or stability. A test with good reliability means that the test taker will obtain the same test score over repeated testing as long as no other extraneous factors have affected the score. In the real world, of course, a test taker will rarely obtain the exact same score over repeated testing. The reason for this is that repeated assessments of any phenomenon will always be affected by chance errors. Thus, the goal of testing is to minimize chance errors and maximize the reliability of the measurement with the recognition that a perfectly reliable measure is unattainable. Although a highly reliable test will not yield identical scores for a participant from Time 1 to Time 2, the scores will tend to be similar. For example, on a 7-point Likert scale, a participant whose score is high on an item at Time 1 will tend to score high on that same item at Time 2. The reliability of a test must be established before its validity can be determined (the validity of a test is the extent to which a test accurately measures the construct that it purports to measure). Yet reliability alone does not indicate that the measurement accurately assesses the concept in question. Thus, a measure of IQ may be highly reliable, yielding consistent scores over long periods of time, but it may not be an accurate measure of the concept of intelligence. Reliability is only the first step in establishing the scientific acceptance of a measure, but it is a required step. The two most common forms of reliability are test-retest reliability and scale reliability.

Test-retest reliability is a measure of a test's consistency over a period of time. Test-retest reliability assumes that the construct being measured is relatively stable over time, such as personality temperaments or intelligence. A good test manual should specify the sample, reliability coefficient, and the length of the test-retest interval. Manuals for most popular objective tests report intervals of about one week to one month. If the trait is likely to change over time (e.g., state anxiety), test makers generally choose a shorter interval (e.g., one week). Test-retest reliabilities are reported and interpreted as correlation coefficients. Test-retest reliabilities are considered to be excellent if they are .90 or better and good if they are about .80 or better. If a trait is thought to be relatively stable but the test-retest reliability coefficient for a test of that trait is around .50, it may mean that the measure is unreliable. There may be too few questions on the test, or the questions may be poorly worded (e.g., double negatives are difficult for nearly everyone). It is also possible that some extraneous variable or variables intervened on the trait during the test-retest interval. One final problem for the interpretation of test-retest reliabilities is that they may be spuriously high because of practice effects or memory effects. A respondent may do better on the second testing because the trait being assessed improves with practice. In addition, some people may respond similarly to a test because they remember many of the answers that they gave on the test earlier. One possible solution to this problem is the use of alternate forms. Some popular tests come with an alternate form, but most do not. If a test user is interested in a trait's change over time and is worried about practice or memory effects, alternate forms of the test may be given.

Scale reliability (commonly called internal consistency) is a measure of how well the items on a test relate to each other. The most common statistic for scale reliability is

Cronbach's coefficient alpha, which is the virtual standard of scale reliability in objective testing. One intuitive way of interpreting Cronbach's alpha is to view it as an average of all of the correlations of each item with every other item on a test. The alpha coefficient is interpreted much like a correlation coefficient and ranges from 0.00 to 1.00. Values above approximately .80 are considered good and generally reflective of reliable (internally consistent) scales.

The alpha coefficient is dependent, however, on three other variables. First, all things being equal, shorter scales or tests (less than about eight items) will yield lower alpha coefficients than will longer scales or tests. This also means that scales or tests with seven or less items may possess reliability that is not reflected in the alpha coefficient. Scales or tests of 30 or more items will often yield alpha coefficients around .90, and even a random selection of more than about 30 items on a test will meet the minimum standard of internal consistency (e.g., .80). Second, the alpha coefficient is dependent on a high first factor concentration (i.e., the scale or test is measuring a single concept or trait). For example, if there is a scale measuring psychoticism and the items were derived to measure equally two major components of psychoticism (aberrant thinking and social withdrawal), the coefficient alpha will be lower than a different measure of psychoticism that assesses only one underlying concept (like aberrant thinking). Third, the alpha coefficient will be dependent on the number of participants who take the test. A higher number of participants (generally above 200) will yield higher alpha coefficients, whereas a lower number of participants (less than 100) will yield lower alpha coefficients. In summary, the scientific community views values of Cronbach's alpha above .80 as acceptable and reliable. It is also important to note that shorter scales or tests (with fewer than approximately eight items) may still be reliable and yet yield alpha coefficients below .80. Scales or tests with a large number of items (around 30 or more) may sometimes yield spuriously high alpha coefficients. Thus, it is important when evaluating the scale reliability of a test to take into account the number of items, the underlying construct or factor structure, and the number of participants. Once evidence of reliability is firmly established for a test, then validity studies can be initiated.

RELIGION AND HEALTH

Religion and medicine have long been fused in response to illness and death. A common idea across ancient cultures was that sickness was a result of violation of ethical or religious standards. In short, sickness was the result of sin (Kinsley, 1996). Today, the connections between religion and health, both physical and mental, have withstood the scrutiny of scientific inquiry. While methodological difficulties exist, the quality of research into the topic is improving, moving from anecdotal compilations to correlational reports and controlled studies. Work continues on a variety of fronts to better understand the mechanisms linking religion-spirituality and health variables.

Religion and Well-being

Exploratory studies designed to determine the paradigms for wellness across a person's life span consistently name religion as a characteristic necessary for optimal health (Frankel & Hewitt, 1994; Wilcock et al., 1999). Meisenhelder and Chandler (2001) report that high frequency of prayer is associated with greater vitality and general health. Similarly, Ayele, Mulligan, Gheorghiu, and Reyes-Ortiz (1999) report that intrinsic religious activity (e.g., prayer, Bible reading) was significantly positively correlated with life satisfaction. Positive associations between religion and general well-being are evident along the continuum of human aging. Holt and Jenkins (1992) emphasized the importance of religion to older persons and stressed the need for gerontologists to exhibit greater awareness of religion as a health enhancer. Other studies conclude that traditional Judeo-Christian beliefs and behaviors may be related to wellness in later life (Burbank, 1992; Foley, 2000; Fry, 2000; Levin & Chatters, 1998). In an exhaustive examination of 630 data-based studies, Koenig (2001) demonstrated that most mainline religions meeting criteria for traditions and accountability tend to promote positive experiences across the life span.

Religion and Mental Health

Frequency of church attendance has been reported to be negatively related to depression, with frequent churchgoers being about half as likely to be depressed as nonchurchgoers (Koenig, Hays, George, & Blazer, 1997). Woods, Antoni, Ironson, and Kling (1999a, 1999b) report that greater use of religion as a coping mechanism resulted in fewer symptoms of depression and anxiety in two distinct samples of HIV-infected individuals. Another study (Mickley, Carson, & Soeken 1995) theorized that religion can have either a positive (e.g., encouraging social cohesiveness, helping establish meaning in life) or a negative (fostering excessive guilt or shame, using religion as an escape from dealing with life problems) impact on mental health. The same study reported that people who demonstrate high levels of intrinsic religiousness tend to have less depression, less anxiety, and less dysfunctional attention seeking. They also display high levels of ego strength, empathy, and integrated social behavior. Studies suggest that religious-

spiritual resources can buffer psychological distress associated with trauma (Rosik, 2000), bereavement (Golsworthy & Coyle, 2001), and sexual assault (Chang et al., 2001).

Not all studies, however, speak to the positive association between religion and mental health. Higher religiosity scores have been demonstrated to be associated with obsessions (Lewis, 2001), schizotypy (Joseph & Diduca, 2001), and dissociation (Dorahy & Lewis, 2002).

Religion and Physical Health

Pargament, Koenig, Tarakeshwar, and Hahn (2001), in a study of nearly 600 medically ill Americans over the age of 55, found that subjects reporting high religious struggle scores were at significantly greater risk of all-cause mortality than those subjects reporting little religious struggle. Likewise, another study reports that subjects describing themselves as "secular" had a significantly higher risk of myocardial infarction (MI) compared with subjects describing themselves as "religious," and this risk was independent of other, more traditional MI risk variables (Friedlander, Kark, & Stein, 1986). Steffen et al. (2002) reported an association between religious coping and lower ambulatory blood pressure in African Americans. Another study reports that absence of strength and comfort from religion following elective open-heart surgery predicted greater mortality (Oxman, Freeman, & Manheimer, 1995). In an intriguing study, Leibovici (2001) conducted a double-blind, randomized control trial examining the effects of remote prayer on 3,393 adults with bloodstream infection and reported that those subjects who were prayed for displayed significantly shorter hospital stays, shorter duration of fever, and lower death rates than those not prayed for. However, Sloan and Bagiella (2002) and Thoresen and Harris (2002) urge caution in interpreting these studies and speak to the need for rigorous examination of reported associations between religion and health.

Mechanisms

The Immune System

While studies examining the impact of religion on the immune system are few, they are methodologically sound and offer intriguing results. One study reports an inverse relationship between frequent attendance at religious services and interleukin-6, an inflammatory cytokine and putative immune system regulator (Koenig et al., 1997a). Another study (Woods et al., 1999a) reports that subjects displaying high levels of religious behavior (e.g., attending religious services, praying) had significantly higher levels of T-helper inducer cell (CD4+) counts and higher CD4+ percentages. Schaal et al. (1998) reported that religious expression was positively correlated with natural killer (NK) cell number, T-helper cell counts, and total lymphocytes in women with metastatic breast cancer.

Increased Social Support

Religion is often practiced in the fellowship of others. Frequent religious involvement may be associated with better health due to an expansion of the social support network. A long tradition of research in social epidemiology has demonstrated the salutary nature of social support (House, Landis, & Umberson, 1988) as well as social support's ability to exert a strong and positive influence over a person's ability to deal with and recover from serious illness (Cohen & Willis, 1985; Taylor, Falke, Shoptaw, & Lichtman, 1986).

Less Fear of Death

Most major religions speak to a continued and happy existence after life on earth is over. As such, another mechanism in the link between religion and health may be the lessened fear of death that religious people tend to display. Modell and Guerra (1980) reported that fear of death led to significant postsurgical complications in 75% of the patients they studied. In a case review of older men undergoing treatment for advanced throat cancer, Pressman, Larson, Lyons, and Humes (1992) found evidence suggesting that a lack of death anxiety explained as a belief in God played a more important role in mediating surgical anxiety than did other coping abilities.

Less Health-Risking Behaviors

Still another factor in the mechanism linking religion and health may be that religious behavior leads to less participation in those behaviors known to be in direct opposition to good health. Jarvis and Northcott (1987) reviewed the practices of members of nine major religions and found significant differences from nonpracticing controls in two main areas: Most religions (1) prescribe behavior that prevents illness or death or that assists in treatment of sickness and (2) proscribe behavior that is harmful to life or that would hinder treatment. Woods and Ironson (1999), in their examination of the role of religiosity-spirituality in medically ill patients, reported that those patients identifying themselves as religious were more apt to cite their religious beliefs as the reason they did not smoke, did not drink, and chose healthy diets than did those patients not identifying themselves as religious. Several studies report positive correlations between reported religiosity and abstinence from alcohol and controlled substances, as well as responsible sexual activity (Avants et al., 2001; Fierros & Brown, 2002; Hammermeister et al., 2001; Holder et al., 2000; Washington & Moxley, 2001).

Methodological Considerations

While the examination of religion and spirituality's role as factors in physical and mental health has yielded consistently positive results, methodological concerns exist—pri-

marily in defining the construct itself to ensure validity and generalizability of any findings. Some studies define religion as the number of times one attends religious services; others use subject self-identification; and still others use belief in God as their definition of religion. Recent headway has been made in the development of instruments designed to make the distinction between religion and spirituality (Ironson & Woods, 1998). Carefully defining the constructs would not only facilitate assessment, it would also address the often confusing nature of what is being measured when one measures religion.

Another concern relates to inadequate control for potentially moderating or mediating variables in most of the studies published to date. It is possible that what appears at first glance to be an association between religion and health may actually be mediated by social support, healthy diet, or any of a myriad of potentially confounding variables.

RELIGION AND MENTAL HEALTH

Religion is an organized system of beliefs, practices, and rituals designed to facilitate closeness to the sacred or transcendent—whether that be God, a higher power, ultimate truth, or ultimate reality—and to foster an understanding of one's relationship and responsibility to others in living together in a community. Religion includes not only attendance at religious services and involvement in religious community activities involving scripture study or prayer but also private personal religious practices such as prayer, meditation, study of scriptures, reading inspirational literature, and private worship. Religion also includes personal religiousness, degree of religious commitment, and religious motivation (the extent to which religious beliefs are the object of the person's ultimate concern in life).

Mental health includes both positive and negative emotional and cognitive functioning. Positive mental health has to do with constructs such as well-being, life satisfaction, joy, peace, hope, optimism, and meaning and purpose, as well as the ability to engage in satisfying social relationships and productive work. Negative mental health involves dissatisfaction, unhappiness, boredom, meaninglessness, and pessimism, as well as the presence of mental conditions that seriously interfere with social and occupational functioning, such as depressive disorder, anxiety disorder, mania as part of bipolar disorder, schizophrenia and other psychotic disorders, personality disorders, substance abuse, and cognitive disorders.

Until about a decade ago, mental health professionals commonly thought that religion was associated with neurosis and negative health outcomes. Sigmund Freud described religion as the obsessional neurosis of humanity (Freud, 1927). Psychologist Albert Ellis said that "the less religious they are, the more emotionally healthy they will tend to be" (Ellis,1980). Psychiatrist Wendell Watters said, "Christian doctrine and teachings are incompatible with many of the components of sound mental health, notably self-esteem, self-actualization and mastery, good communication skills, related individuation and the establishment of supportive human networks, and the development of healthy sexuality and reproductive responsibility" (Watters, 1992). These statements, however, were typically based on personal experiences and clinical experiences with psychiatric patients, not on unbiased systematic assessment of adults in the general population who for the most part are mentally intact.

In the past 10 years increased attention has been paid to the relationship between religion and mental health, especially in nonpyschiatric populations. What has been found is quite different from what was just suggested by some leaders in the field of mental health. The *Handbook of Religion and Health* (Koenig, McCullough, & Larson, 2001) reviews 724 quantitative studies on the relationship between religion and a wide range of mental health outcomes as described in the definition of mental health just

provided. Nearly 480 of those studies (66%) found a statistically significant relationship between religious involvement and better mental health, greater social support, or less substance abuse. For example, both in the United States, where religion is prevalent, and in Europe, where religious involvement is low, studies find that those who are less religious experience more depression and recover more slowly from depression. A number of clinical trials in patients with depression and anxiety disorders have found that religious interventions achieve faster improvement or remission of symptoms than does secular psychotherapy or no treatment. These studies have involved Christian, Muslim, and Buddhist interventions.

Not only may religious beliefs and practices help to protect against mental disorder and speed recovery, but there is evidence that religious involvement is even more strongly associated with positive emotions. Of a total of 100 studies identified in the preceding review, 79 found statistically significant positive correlations between religiousness and variables such as well-being, hope, and optimism. Of 20 studies examining the relationship between religious involvement and social support, 19 found that the religious person had not only more social support but also a higher quality of support that was more likely to endure over time, especially in situations where the person was physically ill or otherwise unable to reciprocate. Similarly, 15 of 16 studies found that religious people appear to have more purpose and meaning in life than do those who are less religious, especially when experiencing physical illness and disability. Even Sigmund Freud admitted that "only religion can answer the question of the purpose of life. One can hardly be wrong in concluding that the idea of life having a purpose stands and falls with the religious system" (Freud, 1930).

Why is religion generally associated with better mental health? There are quite rational reasons why this might be so. First, as noted earlier, religion provides a positive, optimistic worldview that gives life meaning and purpose and provides hope. Again, this is especially true during times of physical illness, dependency, bereavement, and other situations characterized by powerlessness and loss of control that destroy meaning and foster hopelessness. Second, religion provides rules and regulations to help guide decisions concerning one's self and one's relationships with others. These guidelines often encourage such behaviors as forgiveness, thankfulness, generosity, altruism, and other prosocial activities. They also discourage unhealthy coping behaviors such as alcohol or drug use, sexual indiscretions, and gambling that can destroy both personal and family well-being. As a result, religion may actually help to reduce the amount of stress that a person ultimately experiences. This relationship, however, is complicated by the fact that many people also turn to religion in response to stress.

Third, religion helps to create and maintain social connections that are important for combating isolation and loneliness. Religious motivations for providing support to others (i.e., "Love thy neighbor as thy self"), which are present in all major religious traditions, motivate people to continue to provide support even when they do not feel like doing so. Religion provides intrinsic rewards for altruistic activities that do not depend on reciprocal efforts by the receiver (i.e., God will reward). As people respond to religious teachings to reach out and care for others, they find themselves experiencing greater fulfillment, meaning, and joy. Both the receiving and giving of social support are particularly important at times when people tend to withdraw into themselves, as during physical illness or as they grow older, when there is a tendency to become preoccupied with aches and pains and losses, which often leads to anxiety and depression.

This does not mean that religion is always associated with better mental health or greater personal or social well-being. Religious beliefs can be associated with excessive guilt, anxious ruminations over religious teachings, and prejudice against others and may restrict and limit life rather than make it fuller and more satisfying. In general, however, it appears that the positive influences of religion on mental health outweigh the negative.

REPERTORY GRID METHODS

Developed within personal construct theory, repertory grid methods represent a widely used set of techniques for studying personal and interpersonal systems of meaning. Because of their flexibility, repertory grids (or *repgrids*) have been used in approximately 3,000 studies of a broad variety of topics, ranging from children's understandings of physical science principles and consumer preferences to formal structures of self-reflection within cognitive science and the mutual validation of belief systems between friends. However, their most consistent area of application has probably been in the clinical domain, where grids have

been used to assess the properties of meaning systems of different groups of persons (e.g., those diagnosed as thought disordered or agoraphobic), and how these change over the course of treatment.

The role construct repertory test (or *reptest*) was initially designed by George Kelly, the author of personal construct psychology (PCP), as a means of assessing the content of an individual's repertory of role constructs—the unique system of interconnected meanings that define his or her perceived relationships to others. In its simplest form, the reptest requires the respondent to compare and contrast successive sets of three significant people (e.g., my mother, my father, and myself) and to formulate some important way in which two of the figures are alike and different from the third. For example, if prompted with the previous triad, a person might respond, "Well, my mother and I are very trusting of people, whereas my dad is always suspicious of their motives."

This basic dimension, being trusting of people rather than suspicious of their motives, would then be considered one of the significant themes or constructs that the person uses to organize, interpret, and approach the social world, as well as to define his or her role in it. By presenting the respondent with a large number of triads of varying elements (e.g., a previous romantic partner, best friend, a disliked person, one's ideal self), the reptest elicits a broad sampling of the personal constructs that constitute the person's outlook on life and perceived alternatives. These constructs can then be interpreted impressionistically, used as the basis for further interviewing of the respondent, or categorized using any of a number of reliable systems of content analysis, conducted either manually or using available computer programs.

Although the results of the reptest are often revealing, most contemporary users prefer to extend the method beyond the simple elicitation of constructs by prompting the respondent subsequently to rate or rank each of the elements (e.g., people) on the resulting construct dimensions. For example, using the triadic comparison method just described, a respondent might generate a set of 15 constructs (e.g., trusting vs. suspicious; moved by feelings vs. rational; has ambition vs. no goals; young vs. old), which might be arrayed in 15 rows on a sheet of paper. She might then be asked to assign a number to each of 10 elements (e.g., my mother, father, self, partner) arranged in columns going across the sheet, representing where each figure would fall on, say, a 7-point scale anchored by the poles of each construct. For instance, "mother" might be seen as 1 on trusting versus suspicious, representing very trusting, whereas "father" might be placed at 5 on this same scale, representing moderately suspicious. The intersection of the 15 construct rows with the 10 element columns forms the grid, and the matrix of 150 specific ratings it contains is amenable to a wide range of analyses. In practice, repertory grids can be virtually any size, from six constructs and elements to literally hundreds of each for a given respondent. However, most research indicates that the amount of new information about the person's meaning system in a domain (e.g., perceptions of acquaintances) begins to peak once approximately 15 to 20 constructs and a similar number of elements have been sampled. Although the repgrid was originally devised as an interview-based or paper-and-pencil measure, most contemporary users rely on any of a number of computer programs for their elicitation and analysis, such as the popular *WebGrid II* program available via the Internet.

Although the specific element ratings on important constructs are often informative in themselves (e.g., seeing that a respondent views her father as suspicious and having no goals, but also as rational), it is typically more helpful to conduct a comprehensive analysis of the grid to discern larger patterns. This might involve correlating and factor analyzing the matrix of ratings to see at a glance which constructs "go together" for the respondent (e.g., everyone who is trusting may also be seen as moved by feelings), or to learn what people are most and least alike in the respondent's view. These linkages among constructs often suggest why people remain stuck in symptomatic patterns, as when a client resists reconstruing himself as happy instead of depressed because the former is associated with being superficial as opposed to deep. Similarly, patterns of identification among elements in a grid can be clinically informative, and some of these (e.g., degree of correlation between actual self and ideal self) may provide useful indexes of progress in psychotherapy.

An interesting feature of grid technique is that it combines aspects of both idiographic assessment, which strives to reveal unique dimensions of a given respondent's outlook, and nomothetic research, which seeks general patterns across people. Thus, the format of the repgrid essentially guides the respondent in constructing his or her own questionnaire (by eliciting the individual's own constructs and relevant elements or figures to rate) while permitting comparisons across different people or groups. For example, depressed individuals, relative to others, tend to show not only distinctive themes in the content of their constructs (e.g., more self-references and more morally evaluative themes) but also distinctive overall structure (e.g., tighter intercorrelations among constructs and more polarized or extreme perceptions). This blend of projective and objective testing has made grid technique useful to both clinicians and scientists seeking to understand how different persons and groups organize their view of themselves and the world.

Describing a few of the problems to which repgrids have been applied gives some idea about the range and flexibility of the method. Grids have been used to study the long-term adjustment of survivors of incest, who carry with them a sense of distance from other people decades after the sexual abuse. They have also been used to measure processes of identification with other clients and therapists within group therapy settings and to predict who is most likely to

benefit from this form of treatment. Grids have been applied to the study of the development and breakdown of romantic relationships and friendships, by looking at the degree of convergence between partners in the way they construe experiences at increasingly intimate levels. Other investigators have relied on grids to understand the distinctive differences in the knowledge structures of experts and novices in a given domain and to refine the discriminations made by assembly line workers in detecting product flaws. As the use of these methods continues to grow with the dissemination of ever more powerful computerized systems for their elicitation and analysis, it seems likely that repertory grids will become an increasingly popular tool for both helping professionals and social scientists.

REPRESSION

One of the cornerstones of psychoanalytic theory and therapy is the psychological defense mechanism that protects a person from unwanted or unbearable feelings, impulses, or memories. Throughout his life Sigmund Freud, the founder of psychoanalysis, claimed that the purpose of psychoanalytic therapy was to lift the repression that excluded unacceptable mental contents from awareness and to "make the unconscious conscious." In 1893 he and his collaborator Josef Breuer argued that repression operated on memories of traumatic events and that allowing these memories back into consciousness, together with the emotion that originally accompanied them, could bring about a permanent cure for hysteria. In 1896 Freud adapted this idea and claimed a unique role for the repression of memories of early sexual traumas. By the beginning of the new century he had already abandoned this stance in favour of the position which was to become part of mainstream psychoanalysis, namely that repression operated primarily on infantile drives and wishes rather than on memories of actual events.

What did Freud mean by *repression*? He used the term in two main ways and often failed to distinguish between them. One usage referred to a process whereby unwanted material is turned away before it reaches awareness at all (Freud called this *primary repression*). Rather than quietly remaining in the unconscious, however, this material is likely to reenter awareness in disguised ways, such as in slips of the tongue. In his second usage of the term, Freud proposed that a person becomes aware of unwanted mental contents (such as derivatives of this original repressed material) and then deliberately attempts to exclude them from consciousness (Freud called this *repression proper* or *after-expulsion*).

Although there is little empirical evidence to support the notion of primary repression, many contemporary memory researchers would have little problem with Freud's other use of the term. Originally, psychologists saw forgetting as being simply a passive process involving the gradual decay of the memory trace over time or the trace being made less accessible because of interference by later learning of similar material. Today it is widely believed that efficient mental functioning depends on flexible excitatory and inhibitory mechanisms that select relevant material and exclude unwanted material from entering consciousness. In a number of different types of experiments, researchers have found that people who are instructed to forget certain items because they are irrelevant, or who repeatedly practice ignoring them and retrieving something else, do find it harder to remember these items later. A plausible explanation is that these effects are due to an inhibitory mechanism preventing the retrieval of the to-be-forgotten items, a concept that is not dissimilar from after-expulsion.

Intriguingly, there appears to be a substantial group of people (*repressors*) who have difficulty in recalling negative information, although they are no different from others when it comes to positive information. They also tend to deny feeling anxious even when there is physiological evidence that they are highly aroused. Repressors consistently take longer to recall negative incidents from their own past, although they are no slower to recall positive incidents. They are also more successful at forgetting negative material when instructed to do so in an experimental task. With these characteristics, most memory theorists would expect their lives to have been happier than average, but in fact the opposite seems to be the case. These paradoxical findings are consistent with the idea of defense mechanisms posited by psychoanalytic theory.

Do these experimental findings generalize, so that people may first forget and later remember not just words but also significant traumatic incidents that they have experienced? A growing number of prospective and retrospective studies have found that a substantial proportion of clients in therapy for the effects of child sexual abuse (some-

where between 20% and 60%) report having periods in their lives (often lasting for several years) when they could not remember that the abuse had taken place. People have reported forgetting nonsexual as well as sexual traumas, and many of the incidents have received some corroboration. Consistent with Breuer and Freud's original observations, the recovery of many of these memories was accompanied by intense emotion. These recent findings strongly suggest that it is indeed possible to forget and later remember traumatic incidents but do not say anything about whether repression is the mechanism involved or rule out the likelihood that some seemingly recovered memories may not be accurate. Some researchers have speculated that deliberate forgetting, motivated by fear of the consequences of disclosure or of the disruption of close attachments, could help to explain how children abused by someone they know well could come to forget their ill-treatment. Repeated ignoring of the abuse and rehearsal of positive interactions with the perpetrator could have the effect of preventing recall of abusive interactions and reduce the long-term accessibility of these memories.

Freud's emphasis on the importance of defenses against unwanted mental contents and his analysis of some symptoms in these terms have clearly been borne out. Repression, in the sense of a deliberate attempt to exclude unwanted thoughts, feelings, or memories, no longer seems an outlandish notion but has parallels in our modern view of memory and forgetting. The systematic mental avoidance and forgetting of disturbing material appears to be both possible and reasonably common among people who have been traumatized, although the mechanisms are not yet understood. Other aspects of the theory of repression have not been supported, however. The notions of repression as a fully unconscious defense, or as one that is directed at infantile wishes and feelings, have not received empirical support. If anything, it is the earlier 1893 formulation of Breuer and Freud that has benefited most from recent empirical studies. Another primary tenet, that the lifting of repression is the essential element in recovery, has also not been supported. Freud had already discovered by the mid-1890s that its therapeutic value was very limited, but this did not stop him from continuing to place it at the core of the psychoanalytic method.

RESEARCH METHODOLOGY

A general axiom of science is that there is no knowledge without comparison. Measurement in psychology generally is rather imprecise. There are also a relatively large number of variables, and these variables vary over time. Thus the creativity of the researchers enters.

To be able to infer a causal relationship is called the *internal validity* of the research design. Finally, these research relationships and cause-and-effect statements must be shown to generalize, which is called the *external validity.*

Experimental versus Passive Observational Research Designs

There are two broad types of research design: experimental research designs and passive observational designs. In the first type, variables are systematically imposed on or withheld from the subjects. In the passive observational design the researcher merely observes participants under many natural conditions and records the participants' scores and describes their condition and surroundings.

True Experiments

Within experimental designs, there are two major subtypes: true experiments and quasi-experiments. In true experiments, the participants involved in the research are randomly allocated to experimental groups and control groups.

Quasi-experiments

In quasi-experiments no random allocation of participants to groups has been made. Quasi-experiment groups are formed naturally or via the intervention of others. Further, pretreatment measures also must be available. A major difference in the quasi-experiment is that often the groups are unequal initially. However, many times in quasi-experiments groups do differ initially. After experimental treatment, they may be either more different or less different on the criteria than they were initially. Either way suggests that the treatment may cause the effect.

A major type of quasi-experiment is the interrupted time series design. It occurs when participants are observed periodically over time and a treatment is applied or a condition arises at some point or at several specified points in that time span.

Passive Observational Research Design

The second major classification of research designs is the passive observational type—those that are not experimental and often involve intrinsic variables that cannot be applied and withheld, such as socioeconomic level, grade point average, and intelligence level. The passive observational studies can be categorized into four major types of research designs: prediction and classification, sampling and survey, quantitative descriptive, and qualitative descriptive. These

last two categories especially encompass a very large number of variations and methods.

Prediction and Classification

These involve K variables, $K - 1$ of which are used to predict the future (or even current) status, and the Kth variable is a predicted interval variable. In classification analyses, the Kth variable defines classification categories such as college major or religious affiliation. It is known from Sawyer's 1966 study that all types of data available should be used. The results of regression procedures for prediction have never been surpassed.

Sampling and Survey Studies

The purpose of this design is to describe a large population. It is done by selecting a representative group, called the sample, from the population and making the descriptive observations.

Quantitative Descriptive Design

This design also includes a large number of variations. Typically, the observations are made at or near one interval of time on a single group. All observations are quantified via the use of ratings, scales, test scores, and the like.

Qualitative Descriptive Design

Qualitative research is used to discover new variables and new relationships among old and new variables. Some of the methods and areas included in this broad natural observational category are case study, ecological, psychoanalytical, social, clinical, and personality. This type of research is of major use where only one or a small number of participants are involved.

Threats to Internal Validity

Findings in any research can occur by chance alone as the result of naturally occurring variability over time and by random fluctuations in measurement systems. This is called instability, and it is controlled by statistical analysis.

It is known that all observed scores on variables (except average scores) are biased, too high and too low. High scores are biased upward, and low scores are biased downward. When used to measure rather atypical subjects, the bias can be marked. Future observations are expected to change and to be nearer to the average. This threat to internal validity is called regression toward the mean. "Threats to internal validity" is the phrase in research design that interpreters of data use to describe the set of questions they have about possible inaccuracies in interpretation of cause-and-effect relationships among research variables.

Maturation is another threat because participants grow and develop on their own with the passage of time irrespective of what a researcher does to them. Mortality is the systematic reduction of groups of participants because of dropouts, absences, people moving away, and so on. Selection is the systematic choosing or self-selection of people for a treatment or condition who may be different for some groups before the treatment. History is the threat that involves changes in conditions surrounding the research. Instrumentation is a threat that involves changes in the observers' standards over time. Testing involves the distinct effect of gains in participants' scores simply as the result of having previously taken a test.

There are also four affective threats to internal validity: imitation, compensatory rivalry, compensatory equalization, and demoralization. These result from emotional changes in subjects and administrators to adjust for the fact that they were not "favored" by receiving an experimental treatment.

External Validity and Meta-analysis

Finally, external validity is the sum of the characteristics of research that allow the cause-and-effect statements made (as the result of good internal validity) to be generalized to participants, treatments, and criteria not used in the research but similar to them.

Meta-analysis

The external validity of research findings is markedly enhanced when a number of studies of the same general treatment variable can be combined. This procedure is called meta-analysis. In meta-analysis, the major conditions of the research on the criterion variables and the strength of treatment effect are determined. The relationship of most interest is the set of research condition variables and the criterion variable. As the result of this analysis, numerous research condition variables may be shown to have no influence on a set of criteria, and therefore researchers can generalize the results from a number of studies without regard to these extraneous conditions.

RESIDENTIAL ALTERNATIVES

Throughout the course of one's life, the need for residential care may arise. This need may be generated by a variety of reasons, such as a need for physical rehabilitation, or because of mental or physical illness, loss of shelter, or old age.

The current trend in residential alternatives is toward person-centered planning, in which individuals choose where and with whom they live (Braddock, Hemp, Bacfedler, & Fujina, 1995). This trend typically employs natural environments as the venue for such services. Natural environments might be the person's own home with supports or another house or apartment where supports are shared.

Sometimes, however, a natural environment is not indicated for an individual, and there are many other specialized residential alternatives for people who require more care. Residential alternatives most often are thought to be institutions, emergency shelters, orphanages, and nursing homes. These, however, are but a few of the alternatives available for people in need of care. The following are some of the other residential alternatives.

A *boarding home* is one in which unrelated individuals reside without supervision. Most boarding homes are privately operated and serve as a less expensive alternative to apartment or home living. The term *hospice* is often used interchangeably with boarding home.

Convalescent hospitals afford long-term residential care for those who require extensive rehabilitation or nursing care or who are terminally ill. Convalescent hospitals can be privately or publicly operated.

Foster homes are provided by families who open their houses to children who require shelter. Most children who receive foster care require such service because of the loss of parents or guardians. Foster care may be provided for developmentally disabled children who require specialized training outside of their natural homes. Foster parents are usually trained in effective parenting practices and are usually paid for their services by state or county social service agencies. Foster parents are not adoptive parents, as adoption results in a legal name change for the child, as well as legal guardianship of the child by the adoptive parent.

Group homes are provided by public and private agencies for children and adults who require supervised residential care. Unlike foster care programs, group homes generally have up to eight unrelated people residing with supervisory personnel. These supervisory personnel are identified as teaching parents by Fixsen, Wolf, and Phillips (1973) and as house parents/house couples by Holmes (1998).

The very name *halfway house* connotes a transition home. Generally, halfway houses are operated by public or private agencies for the express purpose of facilitating a person's movement from a highly supervised residential setting to independence in the community. Halfway houses also have been called *transitional homes.*

An *intermediate care facility* offers residential services to people with developmental disabilities. Unlike group homes, many intermediate care facilities are located on institutional grounds and follow a medical model, according to Stripling and Ames (1977). Intermediate care facilities are sponsored by the federal government but are administered by the states.

A *nursing home* is a privately or publicly operated long-term care setting for the terminally ill, handicapped, or aged. Unlike convalescent hospitals, nursing homes do not have ready access to all the necessary life-support services that some long-term convalescent patients require.

An *orphanage* is a residential care center designed to offer shelter to homeless children. Unlike foster care settings, most orphanages are operated by religious organizations, but a few are sponsored by public and nonsectarian private agencies.

A *psychiatric hospital* is a residential hospital designed primarily for persons requiring psychiatric care. Unlike institutions for individuals with developmental disabilities, psychiatric hospitals specialize in offering services to the mentally ill. Most psychiatric hospitals are publicly operated.

A *residential school* is one in which the educational training programs are located on the same premises or under the same auspices as the residential program. Residential schools are available to children with or without special needs in the form of preparatory schools. Residential schools can be either privately or publicly operated.

Respite care is a short-term residential service provided to individuals who require temporary shelter, primarily in cases of emergency, family crisis, family vacation, or trial separation. Respite care services can be found as a subunit in many private or public residential settings or in centers designed solely for such services.

A *retirement home* is a residential alternative designed specifically for senior citizens. Retirement homes can follow many different models, including boarding homes, residential cottages, and apartments. Most retirement homes are privately operated.

A *sanitorium* is a residential alternative designed for the treatment of chronic disease and disorders, such as tuberculosis and various forms of mental illness. Sanitoriums generally follow a medical hospital model for service delivery. Most sanitoriums are publicly operated.

A *state school* is an institutional school for children with special needs. Not unlike many residential schools, state schools have residences and educational-training opportunities located on the same site. To a large extent, a cottage residence model is followed at state schools. State schools are publicly operated.

Supervised apartments are living alternatives for adults with special needs who are capable of independent living (Holmes, 1990). Supervised apartments can be found either in clusters or randomly located in an apartment complex. People residing in supervised apartments are regularly mon-

itored by human services personnel to make certain that their personal and social needs are being met. Supervised apartments can be either privately or publicly sponsored.

RETICULAR ACTIVATING SYSTEM

The ascending reticular activating system (ARAS) is the collection of anatomical and neurochemical systems proposed to underlie cortical electroencephalographic signs of arousal and the correlated behavioral activities of alerting and attention. The concept of the ARAS was first formulated by Moruzzi and Magoun in 1949. Based on the effects of either stimulation or destruction of parts of the reticular formation of the brain stem, these authors concluded that “a background of maintained activity within this ascending brain stem activating system may account for wakefulness, while reduction of its activity either naturally, by barbiturates, or by experimental injury and disease, may respectively precipitate normal sleep, contribute to anesthesia, or produce pathological somnolence.” While the accuracy of this prescient formulation has occasionally been challenged during the past 50 years, its general validity is still recognized, and its underlying neural substrates have been described.

The anatomical basis of the ARAS is the reticular formation (RF). The RF extends from the caudal medulla to the rostral midbrain. Its neurons form the core of the brain stem, in which are embedded the specific nuclear groups that supply the cranial nerves with axons. The ascending and descending long sensory and motor pathways of the brain stem pass through and around the reticular formation. Its neurons tend to have long axons with many branches. For example, a single RF neuron may have an axon that branches to reach the dorsal column nuclei, the spinal cord, and the hypothalamus. Because of such extensive branching, the neurons of the RF are capable of exerting profound effects on the general level of activity of the brain and spinal cord.

Projections from the RF to the diencephalon are involved in behavioral and electroencephalographic arousal and correspond to the ARAS. There are at least three aspects of arousal: (1) altering of consciousness to become more alert, often with increased concentration on selected stimuli; (2) appearance of orienting reactions if arousal is produced by introduction of a novel stimulus; and (3) desynchronization of the electroencephalogram (EEG).

The RF influences arousal through two anatomically distinct routes. One pathway extends from the RF through the hypothalamus, ventral thalamus, and basal forebrain to influence the cortex; this pathway is most probably involved in producing generalized arousal that makes the differences between sleep and waking. The second pathway extends from the RF to the reticular and intralaminar nuclei of the dorsal thalamus and probably participates in alerting reactions and alpha blocking.

In addition to having different pathways by which it influences different aspects of arousal, the RF can be divided into nuclear groupings according to anatomical and neurochemical criteria. The most convenient anatomical categorization is made along the medial-lateral dimension. The raphe nuclei are found in the midline of the RF. A large-celled region is found in the central core of the RF, and a small-celled division is located in its lateral portion. These large, medial-lateral divisions may be subdivided along the rostral-caudal length of the RF. The nucleus gigantocellularis is the large-celled nucleus of the medulla. It gives rise to reticulospinal axons that influence movement. In the pons, the nuclei pontis caudalis and oralis take the place of the nucleus gigantocellularis and also give rise to reticulospinal axons. However, these nuclei, especially the rostral-lying pontis-oralis, have many ascending projections and are involved in regulation of cortical arousal.

Some reticular nuclei may also be defined according to neurotransmitter content. Nuclei that contain norepinephrine have been identified in the medullary and pontine RF. The most extensively studied of these is the locus coeruleus. The ascending projections of this nucleus are involved in increasing wakefulness and in selective attention and may be involved in alternating between non-REM (slow-wave) and REM sleep. Dopamine-containing neurons are found in several nuclei of the midbrain tegmental area. The best known of these nuclei is the substantia nigra. Loss of the dopaminergic neurons from the substantia nigra leads to Parkinsonism. There is some evidence that other dopaminergic nuclei participate in maintenance of waking, possibly by influencing the hypothalamus. Some nuclei within the rostral reticular formation utilize acetylcholine as a transmitter; their output forms the part of the ARAS that includes

the ventral thalamus and basal forebrain. They may also influence other reticular formation regions to regulate REM sleep. Serotonin, the neurotransmitter produced by the raphe nuclei, has also been implicated in modulation of arousal. Lesions of the raphe or inhibition of serotonin synthesis produces insomnia. The insomnia induced by reduction in serotonin decreases with time after the insult, suggesting an alternative pathway for decreasing arousal. However, the marked initial effects of destruction of the raphe or permanent inhibition of serotonin synthesis, contrasted with the fact that enhancement of serotonin levels leads to decreased electrocortical arousal and slow-wave sleep, suggest an important role for this transmitter in the regulation of arousal.

RETT SYNDROME

Rett syndrome is a pervasive neurodevelopmental disorder that affects almost solely females. It is marked by a period of apparently normal development for 6–18 months followed by rapid and severe physical and mental deterioration (Brown & Hoadley, 1999). Many of the handicapping features of Rett syndrome stem from apraxia or dyspraxia (inability to perform voluntary motor movements), which interferes with virtually every body movement. The apraxia and absence of verbal skills make assessment of intelligence difficult, but most affected girls ultimately test in the severely retarded range. The syndrome appears to be an X-linked dominant disorder largely owing to a mutation of the methyl-CpG-binding protein 2 gene (MeCP2; Van den Veyver & Zoghbi, 2000).

Although estimates vary, Rett syndrome occurs in about 1 in every 15,000 female births worldwide and affects all racial and ethnic groups. Occurrence appears to be random. Recurrence rates within the same family are less than .4%, indicating that most cases arise through spontaneous mutation (International Rett Syndrome Association [IRSA], 2002). A few males have had symptoms similar to those of Rett syndrome (developmental regression, loss of the ability to walk and make purposeful hand and finger movements, progressive scoliosis, and seizures), but none has had classic Rett. The possibility that males with the syndrome may have a more severe form of the disorder is supported by a report of severe neonatal encephalopathy and infant death of the brother of a girl with Rett syndrome. The infant boy and his sister had the same MECP2 gene mutation (Geerdink et al., 2002). Rett syndrome is apparently lethal prenatally to most affected males.

Rett syndrome has necessary, supportive, and exclusionary criteria. Necessary characteristics include

1. Apparently normal pre-, peri-, and early postnatal development
2. Deceleration of head growth beginning from 3 months to 3 years of age
3. Loss of acquired skills (voluntary hand skills, verbal and nonverbal communication skills) beginning from 3 months to 3 years of age
4. Appearance of obvious mental retardation in early childhood
5. Appearance of intense and persistent hand stereotypies, including hand wringing, squeezing, washing, patting, and rubbing and mouthing and tongue pulling
6. Gait abnormalities in ambulatory cases

Supportive criteria include breathing dysfunctions, bloating and marked air swallowing, electroencephalogram abnormalities, seizures, spasticity, muscle wasting, peripheral vasomotor disturbances, scoliosis, hypotrophic small and cold feet, and growth retardation. Exclusionary criteria include signs of storage disease, retinopathy or optic atrophy, microcephaly at birth, existence of metabolic or other hereditary degenerative disorder, neurological disorder from severe infection or head trauma, intrauterine growth retardation, and peri- or postnatal brain damage. The syndrome may also appear in atypical variants that may be diagnosed in females showing at least three primary and five supportive criteria for classic Rett syndrome. Less restrictive criteria may also be used when evaluating males with symptoms suggestive of Rett.

Classic Rett syndrome generally develops through a four-stage sequence of behavioral and physical changes first described by Hagberg and Witt-Engerström (1986). However, not all affected children show all the features of each stage, and the age of onset, duration of transition from stage to another, and duration of each stage are highly variable. The stages can be summarized as follows:

1. Early-onset stagnation (begins around 6–18 months; duration of months). Developmental stagnation, de-

celeration of head growth, hyptonia; diminished eye contact, communication, hand-use ability; diminished interest in play and the environment; development of random movements

2. Rapid developmental regression (begins around 12–36 months; duration of weeks to months). Appearance of hand stereotypies, including hand wringing, washing, and mouthing; onset of sleep disturbances, breathing irregularities, and seizure-like spells; deterioration of cognitive functioning, hand use, and expressive language; appearance of behavior that may resemble, and be diagnosed as, autism
3. Pseudostationary (begins around preschool age; duration until about 10 years of age). Decrease in autistic-like features; gait and stance become fixed; increased severity of mental retardation, breathing irregularities, bruxism, body rigidity, and seizures; development of scoliosis
4. Late motor deterioration (begins around 10 years of age; duration lifelong). Loss of or decrease in expressive or receptive language and any remaining motor functions, including chewing, swallowing, and walking; increase in rigidity, scoliosis, and muscle wasting.

No cure or effective treatment for Rett syndrome is available, although some symptoms can be managed. Treatment is specific to the individual and the severity of the symptoms at any particular time. A multidisciplinary approach is necessary, typically beginning with treatment by a neurologist and developmental pediatrician. Lifelong physical, occupational, and speech therapy are often necessary, as are academic, social, vocational, and supportive services. Each symptom needs a specific treatment for alleviation, such as medication for seizures and agitation, and braces, surgery, and physical therapy for scoliosis (IRSA, 2002; *WE MOVE*, 2002). Behavior modification has had limited effectiveness in treating the syndrome (e.g., Brown & Hoadley, 1999).

A child diagnosed with Rett syndrome will live well into her 40s, but quality of life is severely compromised at best. Some functioning may show brief spontaneous recovery, but prognosis is poor, and the progressive course of the disorder is currently irreversible. Affected girls will require lifelong close care and supervision, placing a heavy burden on their caretakers. Families may benefit from early and maintained counseling (Brown & Hoadley, 1999).

The recent discovery of the genetic basis and advances in biotechnology have led to several promising avenues of research. These include discovering the mechanisms by which the mutated MeCP2 gene manifests itself; determining how to silence the effects of the mutation; and developing treatment, such as stem cell transplants, that may halt or reverse the course of the disorder (National Institute of Health, 2001).

REWARDS AND INTRINSIC INTEREST

It is usually assumed that giving rewards for performing a task increases future motivation for and engagement in that activity. A large body of research supports this assumption (Baldwin & Baldwin, 1998; Sarafino, 1996). In the early 1970s, however, studies began to find that under certain conditions the opposite effect seemed to occur: External rewards for performing an intrinsically interesting activity *undermined* subsequent interest in and performance of that task.

Demonstrating and Explaining an Undermining Effect of Rewards

The procedure that has generally been used to demonstrate this undermining effect is illustrated by the research of Lepper, Greene, and Nisbett (1973). Preschool children who pretested as being interested in the target activity of drawing with magic markers were assigned to reward and control conditions. Some children were shown a Good Player Award that they would get for drawing pictures, but the control subjects were not. After drawing the pictures, the children who expected the reward received it, and the controls did not. Later, all the children were secretly observed while the drawing materials and other activities were

freely available, with no prizes offered to anyone. The children who previously expected and received rewards for drawing spent less time playing with the drawing materials than did those who had not received a reward. This undermining effect was soon demonstrated with older children and college students using a variety of tasks and material rewards (deCharms & Muir, 1978; Lepper & Greene, 1976).

The explanation given by Lepper and his colleagues (1973; Lepper & Greene, 1976) for the undermining effect of rewards is called the *overjustification hypothesis.* If an external reward is offered and provided for engaging in an initially enjoyable task, individuals perceive the target activity as overjustified because a reward is not necessary. They infer that engaging in the activity was "basically motivated by the external contingencies of the situation, rather than by any intrinsic interest in the activity itself" (Lepper et al., 1973, p. 130). Another theory proposes that rewards can reduce feelings of self-determination (Deci & Ryan, 1985).

Current Status of the Undermining Effect

On the face of it, the idea that rewards reduce people's interest in activities that they enjoy seems to contradict common sense and observation. After all, many people get paid for work that they enjoy and continue to work hard even though they receive paychecks. Research since the 1970s has produced mixed findings, and many studies have reported no decrease in interest after people got rewards for performing enjoyable activities (Cameron & Pierce, 1994; Dickinson, 1989; Flora, 1990). The undermining effects of rewards seem to occur only under limited conditions (Eisenberger & Cameron, 1996; but see also Lepper, Keavney, & Drake, 1996; Ryan & Deci, 1996). Rewards sometimes undermine motivation under three conditions:

1. *High initial interest.* Rewards can undermine very high interest but enhance motivation when there is less initial interest (Calder & Staw, 1975; Sarafino & DiMattia, 1978).
2. *Tangible and salient rewards.* Tangible rewards, such as candy or money, sometimes undermine interest in a task, especially if the reward is salient, such as when a child focuses attention on it (Sarafino, 1984). However, praise as a reward usually enhances motivation for the task (Dollinger & Thelen, 1978; Eisenberger & Cameron, 1996).
3. *The norm is for no reward.* If a person believes that people are not normally given a reward for the activity, being given a reward can undermine interest. If the person believes it is normal and appropriate to receive a reward for the activity, however, the reward increases motivation (Staw, Calder, Hess, & Sandelands, 1980).

Finally, when reduced interest does occur, these decrements are usually minor, transient if the person continues to perform the task following the reward, and unlikely at all if performance meets or exceeds stated standards or receives repeated rewards (Dickinson, 1989; Eisenberger & Cameron, 1996). Thus it appears that rewards can undermine people's interest in enjoyable activities under limited conditions, but the likelihood, strength, and durability of these effects are slight.

RHYTHM

The concept of rhythm has many meanings. The broadest definition that covers all meanings of the word seems to be that of Plato: "Rhythm is order in movement." One might instead propose: "Rhythm is order in succession."

Patterns of temporal order can be found in areas greatly diverse. Here we consider temporal order in three of these—cosmology, biology, and perception. There are similarities between the first two areas, but neither relates to the third.

Cosmic rhythms are known on the basis of experiences independent in time, such as the rhythm of the seasons; the rhythm of the moon, which affects tides; and especially the rhythm of day and night, which has considerable repercussion on our daily lives.

Biological rhythms are numerous in the vegetable and animal kingdoms. If one considers the organism of the human being alone, almost all the body functions are rhythmical.

These rhythms comply with the different systems whose periodicity is endogenous, but they can play the role of synchronizer as one relates to another. Clearly, as the foundation, there is the nightly rhythm. However, humans can transcend the nightly rhythm for a time, such as by living in artificial conditions, in the far North, or even in space. This circadian rhythm differs for its natural duration in being somewhat longer than 24 hours.

The waking-sleeping rhythm, which is more flexible, also would appear to comply with an oscillating system. One finds it in persons in free-running situations, without the influences of the nightly rhythm. It is used to regulate the lives of astronauts in space where the successions of light and darkness are much more rapid.

Yet, although the waking-sleeping rhythm is profoundly altered by social conditions (night work) or geographic considerations (transmeridian flights), one can ascertain that these new rhythms in the long run can serve as synchronizers for the body temperature rhythm, which then adjusts itself to the rhythm of the activity.

These adaptations are important; not only do feelings of well-being or weariness depend on the temperature rhythm, but also degrees of alertness and often levels of performance are affected.

These rhythms then are defined as endogenous; their period of time scarcely varies, but their phases can be displaced through synchronization with a rhythm of the same time period (e.g., the influence of activity rhythm on temperature).

Next we find rhythms acquired through habit (conditioning). Thus it is with the rhythms of hunger, linked to our eating habits with repercussions on our degree of alertness. Weekly rhythms also exist, related in particular to weekend resting, which, come Monday morning, causes slight difficulties with readaptation to the routine of work, whether in the classroom or in the factory.

Perceptual Rhythms

When one speaks of rhythm, one thinks immediately of music and poetry—that is of the recurrence at equal intervals of one or several elements organized in unified structures. This simple description means that, in these cases, there is a perception of the order in the succession.

The perception of rhythm leads us to ask two fundamental questions: (1) What are the temporal limits in which succession is perceived? and (2) What is the nature of structures that lend themselves to repetition?

Temporal Limits of Perceived Rhythm

As the basis for the perception of rhythm, there is the capacity for apprehending successive elements in a unity analogous to our capacity for apprehending a portion of space in a visual angle.

This capacity for apprehending is often called *psychic present* because it corresponds to a perception in which there are simultaneously successive elements. Such is our ability to perceive a simple phrase, such as a telephone number. The psychological present has limits that relate both to the duration and the nature of the elements. Thus one can perceive the succession of two identical sounds that go from the threshold of 0.1 second to a duration of 1.8 seconds. Beyond this duration, the sounds become elements perceived as independent of each other.

But how many elements can one perceive in this present?

Here one must distinguish discrete elements from those that form a structure. Although we are able to apprehend about five letters of the alphabet presented out of order, we can perceive 12 syllables forming a verse. In a perceived structure, be it repeated or not, we perceive subgroups called chunks. The more a perceptual unity is subdivided, the longer the psychic present can be, under the condition that no internal interval exceeds 1.8 seconds. The regular repetition of equal situations thus no longer gives the perception of merely a unity (as that of a phrase) but of a rhythm, as is the case in music, poetry, and dance.

This leads us to consider the rapidity of succession, or tempo. Tempo is referred to as the rapidity with which the elements of a structure succeed themselves and the structures within themselves.

For the rhythmic unity to be clearly perceived, it is necessary that the duration between elements be sufficiently rapid. In significantly slowing the poetic diction or musical execution, one suppresses the perception of the rhythm.

Rhythmic Structures

Consider the simplest example, in which a single sound is repeated at intervals of 0.4 second. These sounds are perceived as linked to each other. When listened to with care, they are perceived as grouped in twos (more rarely in threes). If one analyzes this perception, one begins to see that these groups appear distinct from each other in one or two aspects—either a lengthening of the duration between the groups (pause) or the accentuation of one of two elements.

Artistic Rhythms

Clearly, artistic rhythms are, in the order of temporality, perceived rhythms. It is important to see whether there is a connection between what is done spontaneously by creative artists and the laws of rhythm derived through experimental procedures.

Temporal Limits

Rhythms produced in poetry and music have periods of duration that register perfectly in the indicated perceptual limits. The average length of the rhythmic measures is 3.2 seconds. For lines of poetry, according to J. E. Wallin, the average duration is 2.7 seconds.

For a number of elements of substructures in music, the composer rarely exceeds six beats, and the listener generally hears units of two or three beats. In poetry, the number of syllables rarely exceeds 12, and each line is scanned in two, three, or four parts by accents or pauses.

The structure of rhythmical units perfectly illustrates the preceding analyses. For want of documents, we know through Aristoxene de Tarente (fourth century B.C.) that rhythm is a succession of durations and that these durations are not arbitrary. There is a minimum of indivisible duration and multiples of this duration by two or three, so that rhythm is analyzed as a more or less complex series of shorts and longs, that is, of series of durations. This is also true of dance, music, and chant—arts that were not dissociated. Such was the case in Greek and Latin poetry. Today, depending on the language and customs, poetry is more of the syllabic type, with regular sequences of accents, and in classical poetry, rhyme provides a supplementary indication.

In the classical music of our time, the composer disposes of a set of durations that are exceedingly numerous because the possible durations are binary divisions of a very long note, the semibreve. This is divided into minims, crotchets, quavers, and so on, without counting further gradations. A composer, in a piece that is homogeneous from the point of view of tempo, makes principal use of two notes that stand in a ratio of two or three (quaver and crotchet, or double quaver-quaver, sometimes double quaver-semiquaver), and this in a proportion of 70% to 80%. Evidently there are short notes, long notes, and silences. We believe that these accidents are the creations of the artist, who seeks to escape the determinisms that demand the preferential use of only two periods of duration, the shortest of which is the most frequent.

How might one explain this spontaneous prevalence, perpetuated by usage, of only two durations in rhythmical structures? One might recall a general law that one often finds working in the domain of perceptions: the understanding of a simplification through a double process of assimilation of the elements only slightly different from each other, and of a distinction that tends to overestimate the differences not reduced by assimilation. But in the case of durations used in rhythms, one must remember the notion of transmitted information. In the scale of absolute perceived durations, it has been established that one cannot distinguish a number of durations greater than two or, at most, three.

Here we see a constraint on temporal perception that has imposed itself on artists of all times. It also imposed itself on those who created an alphabet on the basis of intermittent lengths, such as the Morse code based on a system of dots and dashes.

Rhythms of Movements

To study the laws of rhythm, we have made use of perceptions as well as aspects of motor production. One must first note that perceived rhythms, especially in the arts, are rhythms produced by human motor or verbal activities. There is, in effect, a harmony between the rhythms produced and the rhythms perceived. This harmony manifests itself, in particular, in the fact that heard rhythms elicit a very real motor induction whose movements also are periodic. The phenomenon is observable from the earliest age. A child at the age of 1 year can rock gently upon hearing a rhythmical musical piece, and even adults tend to restrain spontaneous movements upon hearing music.

This spontaneity is also revealed by our difficulty in stressing a beat that, for example, lies between two normal accents, or what is called syncopation. Normally it takes considerable practice to execute two different rhythms with separate hands to create a polyrhythm.

To return to the spontaneous synchronization of music, one clearly sees that the movement accompanies the principal accent point, but if the structure is long and complex, synchronal movements are created with secondary accent points. It all works as though the induced accompanying movements are to remain interlocked, which means that the interval that separates them must be distinctly less than 1.8 seconds.

Motor induction and synchronization give other than

perceptual qualities to the rhythms. The audiomuscular harmony brings about emotional reactions characteristic of the perception of rhythm. Besides, spontaneous synchronization allows for the socialization of rhythmical activities, such as in dance, orchestral music, and choral singing. This socialization of activities is always a source of stimulation.

Spatial Rhythms

One speaks less of spatial rhythm than one does of auditory rhythm. In describing a monument, for example, one speaks more readily of form or proportion. Quite naturally there are successions, but they register in a three-dimensional context, which gives rise to further problems.

When considering only linear successions, it is observed that they often are like rhythmic structures with regular repetitions of identical elements, as a tree-planted avenue, or by a repetition of binary, or even tertiary, structures with regular spacings between the groupings. One may even find in rows of windows, for example, more complex structures with elements that are varied but of a repetitive nature.

P. Fraisse

RIBOSOME

The prokaryotic ribosome represented by the *E. coli* ribosome has a molecular mass of 2.5 million daltons and a volume of 3 million cubic Ås (Yonath & Franceschi, 1998) and is designated a 70S particle. The 70S ribosome has three tRNA binding sites: the acceptor (A), the peptidyl (P), and the exit (E) site. It is made up of dissociable subunits, a 30S subunit (0.8 million) and a 50S subunit (1.7 million). The 30S subunit is a complex of one large RNA strand (16S RNA, 1,542 bases long) and 21 proteins (denoted S1 to S21). The 50S subunit is a complex of two RNA strands (23S rRNA, 2,904 bases long; 5S RNA, 120 bases long) and at least 33 proteins (denoted L1 to L34; there is no L8). X-ray crystallography and nuclear magnetic resonance (NMR) have been applied to determine the high resolution structure of a number of ribosomal proteins and limited regions of RNA and of protein RNA complexes. Thanks to the progress in the crystallography of ribosomes, reasonably accurate structural models for the subunits and for one or two complexes of 70S ribosomes are available (Ban et al., 1998; Moore, 1998; Yonath, private communication, 1998). The relative spatial arrangements of each ribosomal component are now understood (resolution approximately 7–10 Å). In addition, cryoelectron microscopy elucidated the structure of the 70S ribosome and complexed ligands such as tRNA, mRNA, EF-G, and EF-Tu at 7- to 10-Å resolution. Other approaches helping us to understand the structure of ribosomes include neutron scattering, immuno-electron microscopy, fluorescence energy transfer, cross-linking and chemical footprinting. On the basis of the information obtained by these studies, computer-based, three-dimensional models of ribosomes have been built.

The most extensive studies on eukaryotic ribosomes were conducted on rat ribosomes (Wool, Chan, & Gluck, 1996). Although these eukaryotic ribosomes are in principle similar to their prokaryotic counterparts, important differences do exist. Mammalian ribosomes (80S particles) are composed of 40S and 60S subunits. The 40S subunit has 18S RNA and 33 proteins, while the 60S subunit has three RNAs—5S, 5.8S, and 26S—and 47 proteins. Mammalian ribosomal proteins have an average molecular weight of 18,500 and contain 165 amino acids. They are very basic, with an average isoelectric point of 11.05. A common feature of mammalian ribosomal proteins is the repetition of short amino acid sequences, generally of three to eight. The number of genes encoding the ribosomal protein is 12, but there is no evidence that more than one gene is functional. Ribosomal proteins from all eukaryotic species are closely related and appear to be derived from a common ancestral gene.

Function of Ribosomes

The function of ribosomes is to synthesize protein from aminoacyl tRNA according to the information in the messenger RNA (mRNA) with the help of soluble protein factors. Protein synthesis can be divided into four steps: translation initiation, peptide chain elongation, translation, termination (release of the completed chain), and disassembly of the posttermination complex for the recycling of the translational machinery.

Translation Initiation

During the protein synthesis initiation process, the small ribosomal subunit binds to the mRNA and positions the initiation codon of the mRNA into the ribosomal decoding center at the P- (peptidyl-) site. The second codon on the mRNA is at the ribosomal A- (acceptor-) site. The charged initiator tRNA is bound at the ribosomal P-site. The resulting ribosome:mRNA:initiator-tRNA complex is called the initiation complex. Bacteria and organelles (mitochondria and chloroplasts) of eukaryotes form the initiation complex in much the same way. The analogous process in the cytoplasm of the eukaryotes differs from that of prokaryotes in several respects, and the prokaryotic and eukaryotic translation initiations are described separately.

Prokaryotic Translation Initiation. Three soluble factors, IF1, IF2, and IF3, are involved in this process. The first event of the initiation process is the dissociation of the released free 70S ribosome into its large and small subunits via one of the two known functions of IF3 (Gualerzi & Pon, 1990). IF3 also prevents subunit reassociation and helps the 30S subunit

to bind to the initiation site of mRNA. The initiator fMet-tRNA^{fMet} and mRNA, with appropriate initiation signals, bind the 30S subunit. This process takes place in random order (Wu, Iyengar, & RajBhandary, 1996). The initiation site of mRNA usually has the ribosome binding sequence (Shine-Dalgarno [SD] sequence), a few nucleotides (optimally 3–9) upstream of the initiation codon (AUG > GUG > UUG > AUU). Base pairing between this SD sequence and a few nucleotides at the 3′ end of the 16S rRNA is important for the selection of the translational start site of mRNA by the 30S subunit (Hui & De Boer, 1987; Jacob, Santer, & Dahlberg, 1987).

In some cases translation may occur from mRNAs lacking an SD sequence; alternative mechanisms therefore exist (Sprengart & Porter, 1997)—for example, bridging the mRNA to the ribosome by the S1 ribosomal protein, which recognizes U-rich stretches in the 5′ untranslated region. Base pairing with 16S rRNA nucleotides 1082 to 1093 and 1343 to 1355 with the 5′ untranslated sequence of mRNAs plays a role in this case. Other mechanisms include base pairing with 16S rRNA nucleotides 1469 to 1483, with mRNA sequences downstream from the initiation codon.

In all cases, the interaction between the 16S rRNA and the mRNA is such that the initiation codon is positioned at the decoding center of the ribosome in the 1400/1500 nucleotide region of the 3′ end of the 16S rRNA. Association of the 30S subunit and mRNA, and the concomitant translation initiation, may occur at several different initiation points along the bacterial polycistronic mRNA.

IF2, the largest of the three initiation factors, promotes the binding and correct positioning of fMet-tRNA^{fMet} to the P-site of the ribosome and prevents the participation of elongator aminoacyl-tRNA in the initiation process. This is achieved by specific recognition of the blocked (formylated) amino group of initiator fMet-tRNA^{fMet} by IF2 (Hartz, McPheeters, & Gold, 1989; Wu & RajBhandary, 1997). IF2 functions as a carrier of fMet-tRNA^{fMet} to the 30S ribosomal P-site in much the same way as EF-Tu functions as a carrier of aminoacyl-tRNAs to the A-site of 70S ribosomes (see the section Peptide Chain Elongation). The sites of fMet-tRNA^{fMet} contacting IF2 have been studied by footprinting experiments and were found primarily within the T loop and the minor groove of the T stem. The footprints of IF2 on fMet-tRNA^{fMet} in the binary fMet-tRNA^{fMet}·IF2 complex and in the 30S·IF2·fMet-tRNA^{fMet}·AUG complex are similar. This suggests that the interactions between IF2 and either the isolated fMet-tRNA^{fMet} or the P-site-bound fMet-tRNA^{fMet} are essentially the same (Wakao et al., 1989). In addition, IF2 interacts with the 3′ end of the initiator tRNA and protects the ester linkage in fMet-tRNA^{fMet} from deacylation (Petersen, Roll, Grunberg-Manago, & Clark, 1979). No effect of IF2 on the reactivity pattern of the 16S rRNA in the protection assays was seen, suggesting that this factor interacts primarily through protein-protein interactions with the ribosome in the initiation complex (Moazed, Samaha, Gualerzi, & Noller, 1995).

IF3, bound to the 30S subunit, recognizes the anticodon stem of the initiator tRNA and helps to prevent the binding of elongator tRNAs to the 30S initiation complex (Hartz et al., 1989). Furthermore, IF3-dependent protection of 16S rRNA from chemical modification is found in the vicinity of a region that is also protected by P-site–bound tRNA. This indicates that the IF3 may also interact with the anticodon domain of fMet-tRNA^{fMet} or influence the properties of the 30S P-site during initiation (Moazed et al., 1995). The placement of IF3 by cryoelectron microscopy on the 30S subunit allows an understanding in structural terms of the biochemical functions of this initiation factor (McCutcheon et al., 1999).

IF1 is the smallest of the three initiation factors. It stimulates the activity of IF2 and IF3 on formation of the 30S initiation complex. The affinity of IF2 to the ribosome is increased in the presence of IF1 (Gualerzi & Pon, 1990). Footprinting revealed that the binding of IF1 to the 30S ribosomal subunit protects the same nucleotides in 16S rRNA from modification as the EF-Tu–dependent binding of aminoacyl-tRNA to the ribosomal A-site (Moazed et al., 1995). This suggests that during initiation, IF1 binds to the ribosomal A-site at the same position as the anticodon domain of the aminoacyl-tRNA during elongation. Thus, the function of IF1 may be to prevent the premature binding of elongator aminoacyl-tRNA to the A-site during the initiation process, and a complex of IF1 and IF2 interact with the ribosomal A-site, mimicking the structure of the elongation factor G (Brock, Szkaradkiewicz, & Sprinzl, 1998). As these initiation factors and EF-G fulfill a similar function in placing a tRNA to the ribosomal P-site, structural similarities between them may indicate similar molecular mechanisms of action.

The 30S initiation complex forms the 70S initiation complex by association with the 50S ribosomal subunit. Concomitant with this process, IF1 and IF3 are ejected. The process is stimulated by IF2, whose GTPase activity is activated, and IF2 is released upon hydrolysis of GTP. At this stage, the fMet-tRNA^{fMet} is located in the ribosomal P-site, ready to form the first peptide bond. The mechanism of initiation in bacteria has been extensively reviewed (Gualerzi & Pon, 1990; Hartz et al., 1989; RajBhandary & Chow, 1995).

Initiation in the Cytoplasm of Eukaryotic Cells. One peculiar feature of eukaryotic mRNAs is that the 5′ end of most of them has a structure called a cap. This is a structure involving methylated guanine triphospho nucleotide, ^{7}mGpppN, where N denotes any base. Many factors are involved in the eukaryotic initiation process and are designated as eIFs. A cap-dependent mechanism accounts for the translation of the vast majority of cellular mRNAs. An alternative cap-independent initiation mechanism is responsible for translation of a small number of mRNAs (Gray & Wickens, 1998). The process of initiation is similar in germ line cells and during embryogenesis as well (Jackson & Wickens, 1997).

In both the cap-dependent and the cap-independent pathways, the initiation proceeds via formation of a 43S preinitiation complex consisting of the 40S ribosomal subunit, a ternary complex of eIF2·GTP·Met-tRNA$_i^{Met}$ (the initiator tRNA in eukaryotes is not formylated in contrast to its prokaryotic counterpart), and eIF3. Ribosomes at physiological Mg^{2+} concentration (>1 mM) predominantly exist as 80S monosomes. The equilibrium between 80S monosomes and dissociated subunits is shifted toward dissociation by eIF3, eIF1A (alternative name eIF-4C), and eIF3A (alternative name eIF6). EIF3 and eIF1A bind to the 40S subunits, while eIF3A binds to the 60S subunit, making 40S subunits available for initiation (Hershey, 1991; Merrick, 1992; Pain, 1996). EIF1A is a single subunit factor with basic N-terminus and acidic C-terminus.

eIF-3 consists of at least 8 polypeptides in mammalian cells and *S. cerevisiae* and 10 polypeptides in wheat germ cells. This initiation factor remains bound to the 40S subunit and is necessary for the stable binding of the eIF2·GTP·Met-tRNA$_i^{Met}$ ternary complex (Gray & Wickens, 1998; Merrick, 1992; Merrick & Hershey, 1996) to the small subunit. eIF3A (one of the proteins of eIF3 complex), which remains bound to the 60S subunit, is a single subunit protein (Merrick, 1992).

eIF2 consists of three subunits: γ, β, and α. The γ-subunit possesses the GTP-binding elements. In the absence of GTP, eIF2 is not able to bind to initiator tRNA. Based on cross-linking studies, both the γ- and the β-subunits bind to Met-tRNA$_i^{Met}$ (Gaspar et al., 1994). The main known function of the α-subunit is to link translation to regulatory circuits via the presence of a conserved phosphorylation site (Ser51 in mammalian cells) present in its sequence. When the α-subunit is phosphorylated, eIF2 loses its ability to replace its spent GDP with GTP. In addition, the phosphorylated α-subunit segregates the nucleotide exchange factor eIF2B from the rest of eIF2 by tightly binding to it. This makes eIF2B less available for replacing the GDP with GTP on the eIF2·GDP binary complex. As a consequence, availability of the eIF2·GDP·Met-tRNA$_i^{Met}$ ternary complex for the initiation decreases, fewer 43S preinitiation complexes are formed, and translation decreases (Gray & Wickens, 1998; Pain, 1996).

In the cap-dependent pathway, this 43S preinitiation complex is then recruited at the 5′ end of the mRNA, involving the ^{7}mGpppN cap structure on the 5′ end with the association of eIF4 group initiation factors, including 4F and B. The complex is frequently called the 48S preinitiation complex.

The eIF4F consists of three subunits with distinctive functions: eIF4E, eIF4A, and eIF4G. eIF4E is a cap-binding protein; eIF4A has an ATP-dependent RNA helicase activity; and eIF4G has affinity in its N-terminal third to eIF4E (Lamphear, Kirchweger, Skern, & Rhoads, 1995; Mader, Lee, Pause, & Sonenberg, 1995), while its C-terminal two-thirds has affinity to both eIF3 and eIF4A (Lamphear et al., 1995). Therefore, eIF4G bridges the cap structure of the mRNA (via eIF4E), the 40S subunit of the ribosome (via eIF3), and eIF4A (Hentze, 1997; Jackson & Wickens, 1997). Both eIF4E and eIF4G have been shown to participate in regulatory circuits affecting translation in the initiation step (Gray & Wickens, 1998; Hentze, 1997; Jackson & Wickens, 1997).

It has been shown in *S. cerevisiae* that the poly(A) tail-stimulated translation is mediated by a protein, Pab1p, which binds to a stretch of 10 A nucleotides at the 3′-ends of mRNAs. Pab1p acts synergistically with the cap structure but also can work in its absence and exerts its stimulatory effect via binding to the eIF4G.

There is also growing evidence that some signal transduction/phosphorylation systems positively regulate translation via the involvement of eIF4E. Thus, the eIF4E binding protein 1 (4E-BP1) strongly binds eIF4E and sequesters it from entering the eIF4F initiation complex. Phosphorylation of 4E-BP1, elicited, for instance, by insulin, makes eIF4E available for eIF4G binding and hence increases 48S preinitiation complex formation.

Another eIF4 group factor (but not part of eIF4F), eIF4B joins the 48S preinitiation complex and stimulates the unwinding of the secondary structures in the 5′ untranslated region of the mRNA via eIF4A (Lawson et al., 1989; Rozen et al., 1990). EIF4B also interacts with eIF3; this ability may aid in binding the 43S preinitiation complex to the mRNA (Merrick, 1992).

The 40S ribosomal subunit, with the associated initiation factors, has to relocate from the cap through the 5′-untranslated region (5′-UTR) of the mRNA to the site of initiation, which is generally 100 to 150 nucleotides downstream along the mRNA. This process is termed scanning (Kozak, 1978) or shunting (Gray & Wickens, 1998). In the scanning model, the preinitiation complex migrates along the mRNA in a continuous manner from the 5′-UTR to the initiation site. In the shunting model, scanning toward the initiation site is discontinuous; the preinitiation complex hops over secondary mRNA structures, which in themselves are inhibitory for the scanning. The scanning is an ATP-dependent process and is dependent on eIF1 and eIF1A (Pestova et al., 1998).

The scanning preinitiation complex selects the site of initiation generally at the location of the first initiation codon, overwhelmingly AUG but occasionally GUG or CUG (Kozak, 1989, 1994). Sometimes it is not the first initiation codon, mainly when the ORF is preceded by short ORFs (sORFs), and the ORF is not translated when translation of sORF is prevented (Hinnebush, 1996). RNA:RNA interactions may play a role in positioning the initiation codon in the decoding center of the 40S ribosomal subunit, although it is not so apparent as in prokaryotes (Sprengart & Porter, 1997). There is a consensus sequence of approximately 10 nucleotides for the initiation site (Kozak, 1994). The most important positions are a purine, at –3 position, and a G, at +4 position, where A of the initiator AUG codon is position +1. The fidelity of interaction between the codon

and the complementary anticodon loop of the initiator tRNA is controlled by both eIF3 (Naranda, MacMillan, Donahue, & Hershey, 1996) and eIF2 (Pain, 1996).

In the alternative cap-independent initiation pathway, a *cis*-acting mRNA element (the internal ribosome entry segment [IRES]) promotes direct access of the 43S preinitiation complex to the initiation codon and can even allow several cycles of translation of a covalently closed circular mRNA (Chen & Sarnow, 1995). Although IRES is similar in strictly operational terms to the Shine and Dalgarno sequence of prokaryotic mRNAs (Pestova, Shatsky, et al., 1998), IRES is much larger. Internal entry was first discovered with picornavirus RNA, and evidence for its existence has widened since then (Bernstein, Shefler, & Elroy-Stein, 1995; Gan & Rhoads, 1996; Jackson & Kaminski, 1995). Internal initiation of viral mRNA allows some viruses whose mRNAs do not have a cap structure to shut down the translation of most of the cellular mRNAs during viral infection via cleavage of eIF4G. This gives the advantage to the virus, which will then use all cellular protein synthesis machinery for its own replication. The cleavage separates eIF4G into an amino-terminal one-third portion that binds the cap-binding initiation factor eIF4E, and a carboxy-terminal two-thirds fragment that binds eIF3 and the helicase eIF4A.

After the initiation site is selected by the 40S subunits, the 60S ribosomal subunit associates with the complex forming of the 80S ribosome. This step requires eIF5 and the energy of hydrolysis of the GTP bound to eIF2 in the preinitiation complex. The hydrolysis is catalyzed by eIF5, which has GTPase motifs in its sequence (Chakravarti & Maitra, 1993; Das, Chevesich & Maitra, 1993). Upon association of the large subunit, initiation factors are released, and the 80S ribosome is ready to enter the elongation cycle.

Peptide Chain Elongation

For catalyzing peptide chain elongation, the ribosome has three tRNA binding sites: the acceptor (A) site, the peptidyl (P) site, and the exit (E) site (Agrawal & Frank, 1999; Frank, 1997; Moore, 1997, 1998; Nyborg & Liljas, 1998). The ribosomal A-, P-, and E-sites are situated in the cavity between the large and small subunit interface, with the E-site positioned toward the L1 arm side of the large subunit, the A-site positioned toward the L7/L12 arm on the opposite side of the large subunit, and the P-site in between the other two sites. The A- and P-sites span the large and the small subunit, whereas the E-site is localized to the large subunit only.

Peptide chain elongation takes place in the absence of soluble factors, though very slowly (Wilson & Noller, 1998). Under physiological conditions, the prokaryotic ribosome requires elongation factors EF-Tu, EF-Ts, and EF-G. These factors are single-subunit proteins, except for EF-Ts, which forms a dimer (Czworkowski & Moore, 1996; Green & Noller, 1997). In eukaryotes, three factors function for peptide chain elongation: EF-1α (a monomeric protein) corresponds to EF-Tu; eEF-1βγ (composed of two subunits) corresponds to EF-Ts; and eEF-2 (a monomeric protein) corresponds to the prokaryotic EF-G (Hershey, 1991; Merrick, 1992). An additional factor, eEF-3, which stimulates the translation 5- to 30-fold, has been identified only in yeast and fungi (Merrick, 1992). This factor is necessary for the removal of the deacylated tRNA from the E-site, which has a stronger affinity for tRNA in eukaryotes (especially in fungi) than in prokaryotes (Spahn & Nierhaus, 1998).

The repetitive elongation cycle proceeds in three consecutive steps: aminoacyl-tRNA binding to the ribosomal A-site, peptide bond formation, and translocation of the ribosome one codon towards the 3′-end on the mRNA with concomitant translocation of the deacylated tRNA from the P-site to the E-site, and the peptidyl-tRNA from the A-site to the P-site together with the mRNA movement.

In the first step of chain elongation, the elongator aminoacyl-tRNA is brought to the ribosomal A-site as a ternary complex: aminoacyl-tRNA·EF-Tu (EF-1α in the cytoplasm of eukaryotic cells)·GTP (Pape, Wintermeyer, & Rodnina, 1998; Rodnina, Fricke, Kuhn, & Wintermeyer, 1995; Rodnina, Pape, Fricke, Kuhn, & Wintermeyer, 1996; Rodnina, Pape, Fricke, & Wintermeyer, 1995). The initial rapid and reversible phase is a codon-independent complex formation between the ribosome and the ternary complex. With the cognate aminoacyl tRNA, the subsequent event, inducing the GTPase conformation of EF-Tu and the ribosome-induced GTP hydrolysis, proceeds at a rate four orders of magnitude higher than in the case of binding a noncognate ternary complex. The affinity of the cognate aminoacyl tRNA to the A-site is greatly influenced by whether the E-site is occupied with deacylated tRNA according to the allosteric model (described below), because the configuration of ribosomes is greatly influenced by tRNA on the E-site (Spahn & Nierhaus, 1998).

During the binding process, the anticodon end of the aminoacyl tRNA binds to the A-site of the 30S subunit. The opposite end of the complex contacts the L7/L12 region of the 50S subunit, and the amino acid on the acceptor end of the tRNA is held by the elongation factor so that it is not yet accessible for the peptidyl transferase center on the 50S subunit (Krab & Parmeggiani, 1998; Nyborg & Liljas, 1998; Stark et al., 1997). When the GTP of the ternary complex is hydrolyzed by the GTPase activity of the elongation factor, EF-Tu undergoes a second conformational change, which leads to the release of the aminoacyl-tRNA from the ternary complex. Subsequently, in a rotational movement, the acceptor end of the aminoacyl-tRNA becomes positioned into the large subunit part of the A-site and becomes accessible for the peptidyl transferase center on the 50S subunit (accommodation step; Nyborg & Liljas, 1998; Stark et al., 1997). In the eukaryotic system, the binding of aminoacyl tRNA proceeds in a similar way with EF-1α (corresponding to EF-Tu). Because both the prokaryotic EF-Tu and the eukaryotic EF-1α bind GDP with high affinity, an additional

elongation factor, EF-Ts in prokaryotes and EF-1βγ in eukaryotes, helps to regenerate the GTP form of these factors.

The next step is the peptide bond formation. The peptidyl transferase activity is an inherent property of the ribosomes. Peptide bond formation is catalyzed by the large ribosomal subunit (Green & Noller, 1997; Maden, Traut, & Monro, 1968; Nierhaus, Stuhrmann, & Svergun, 1998). The peptidyl-transferase is located at the interface side of the subunit below the central protuberance of the 50S subunit. In vitro ribosome reconstitution experiments and the finding that the peptidyl transferase activity of *Thermus aquaticus* ribosomes is very resistant to protein extraction procedures point to the ribosomal proteins L2, L3, and the 23S rRNA as prime candidates for exerting the activity.

The next step is translocation; but before a discussion of translocation, the two models of the ribosomal tRNA binding site must be introduced. They are the hybrid site (Moazed & Noller, 1989) and the allosteric α-ε–site models (Burkhardt, Junemann, Spahn, & Nierhaus, 1998; Czworkowski & Moore, 1996; Dabrowski, Spahn, Schafer, Patzke, & Nierhaus, 1998; Green & Noller, 1997; Hershey, 1991; Merrick, 1992; Nierhaus, 1990; Nierhaus et al., 1998; Spahn & Nierhaus, 1998; Wilson & Noller, 1998).

In the hybrid site model, the main feature is that one portion of tRNA (3′ end) bound to the large subunit moves independently of the other portion (anticodon part) during peptide chain elongation. Loading of the aminoacyl-tRNA occurs in two well defined steps: In the first step, the aminoacyl-tRNA occupies only the small subunit portion of the A-site; the second step leads to the full occupation of the A-site. Before peptidyl transfer, the peptidyl-tRNA is in the P-site and the aminoacyl tRNA is in the A-site. After the peptidyl transfer (peptide bond synthesis), the peptidyl-tRNA is bound to the A-site of the 30S subunit at the anticodon portion while the acceptor portion of the peptidyl-tRNA with peptide group is bound to the P-site of the large subunit. At the same time, the anticodon portion of the deacylated tRNA (formed as a result of the peptide bond formation) remains at the P-site of the 30S subunit, while the CCA end (the acceptor end) of the tRNA moves to the E-site of the large subunit. Translocation moves the anticodon portion of the deacylated tRNA, together with the mRNA, to the E-site so that the deacylated tRNA fully occupies the E-site. On the other hand, the anticodon portion of the newly elongated peptidyl-tRNA moves, together with the mRNA, to the P-site of the 30S subunit. Thus, the peptidyl-tRNA is now fully situated in the P-site.

The allosteric α-ε model stems from the finding that the ribosomal binding domains of the A-site and of the P-site–bound tRNAs in the pretranslocation state ribosome do not change significantly when these tRNAs are translocated to the P- and E-sites respectively. This suggests that the microenvironment for the tRNAs remains very similar in both states, although there are considerable conformational changes in the ribosome itself. Therefore, the ribosome behaves as if it had a movable block preserving the contact sites for the tRNAs during translocation. The α part of the ribosome preferentially binds an acylated tRNA (aminoacyl or peptidyl tRNA) and covers the A- or P-site. The ε part of the ribosome preferentially binds a decylated tRNA and covers the P- or E-site. At the pretranslocation step, the α part is found only at the A-site; after translocation, the ε part is located exclusively at the E-site. In the posttranslocational state, two high-affinity sites (P and E) exist. It is known that aminoacyl tRNA can bind to the posttranslocational state ribosomes (Triana-Alonso, Chakraburtty, & Nierhaus, 1995) at the A-site. Therefore, the α-ε model postulates the third nonmovable decoding site, ∂. The affinity of the ∂-site is increased when the E-site is emptied due to the allosteric effect of the E-site on the affinity and fidelity of the A-site. The ∂-site is separated from the α-ε domain in the post-state but overlaps with the α domain at the prestate.

Translocation is the movement of the mRNA, tRNA, and ribosome complex by one codon length toward the 3′ end for about 12Å (Wadzack et al., 1997). Two tRNAs are relocated from the A- and P-sites to the P- and E-sites, respectively. The role of EF-G·GTP (eEF-2·GTP in eukaryotes) in this process is mainly to reduce the activation energy barrier between the pre- and the posttranslocational states, which is about 90 kJ/mol under physiological conditions (Schilling-Bartetzko & Nierhaus, 1992). In support of this concept is the fact that in the absence of the elongation factors, translocation is still possible at a reduced speed (Bergemann & Nierhaus, 1983; Schilling-Bartetzko et al., 1992). During the translocation step, the GTP of the elongation factor is hydrolyzed. The EF-G·GDP (eEF-2·GDP in eukaryotes) complex loses its affinity for the ribosome and is released. A striking similarity in the overall shape of the EF-G·GDP (Czworkowski, Wang, Steitz, & Moore, 1994) and the aminoacyl-tRNA·EF-Tu·GTP (Nissen et al., 1995) complexes were found recently. This leads to the speculation that the two macromolecules may share common ribosomal structures for their binding and some kind of common mechanism in their function (Wilson & Noller, 1998).

The elongation cycle is the most energy-requiring process in protein biosynthesis. It essentially takes two high-energy phosphates brought about by elongation factor·GTP complexes and two high-energy phosphates used to generate each aminoacyl-tRNA ($ATP + AA + tRNA \rightarrow AMP + PP_i +$ AA-tRNA). Thus, the formation of each peptide bond costs four high-energy phosphates for the cell.

Translation Termination

When the prokaryotic ribosomes engaged in the peptide chain elongation come to the end of the open reading frame, the termination codon, UAA, UAG, or UGA, is placed in the A-site (acceptor site) of the ribosomes. The release of completed chain takes place at this point with the help of certain factors. With most of the prokaryotes, except for *M. genitalium,* the smallest free-living organism, three soluble

factors RFs (release factors) 1, 2, and 3 are involved. RF1 functions with UAA and UAG, while RF2 functions with UAA and UGA (Scolnick, Tompkins, Caskey, & Nirenberg, 1968). Regions in helix 34 and 44 of the 16S RNA (Brown & Tate, 1994; Goringer, Hijazi, Murgola, & Dahlberg, 1991) have been implicated in the recognition of the stop codon. RF1 and RF2 are composed of two domains, one responsible for recognition of the stop codon and the other responsible for hydrolysis of the ester linkage between 3′ OH of tRNA and COOH of amino acid (Brown & Tate, 1994; Moffat & Tate, 1994). The function of RF3 is to promote the recycling of RF1 (Freistroffer et al., 1997; Grentzmann, 1998). As for the relationship between RF2 and RF3, RF3 either stimulates recycling of RF2 (Freistroffer et al., 1997) or simply promotes the binding of RF2 to the termination complex (Grentzmann et al., 1998). The differential effect of RF3 on RF1 and RF2 is supported by the in vivo experiment in which RF3 was shown to act preferentially on RF2 (Grentzmann et al., 1995). During the action of RF3 in vitro, GTP is required (Grentzmann et al., 1998); this is understandable because RF3 has the GTPase motif (Grentzmann et al., 1994) and ribosome-dependent GTPase activity (Grentzmann et al., 1998).

The process of the completed peptide chain release in eukaryotes is similar but somewhat different. Only two factors, eRF1 and eRF3, are involved. eRF1 functions for recognition of all three termination codons (Frolova et al., 1994), and eRF3 functions as GTPase only in the presence of eRF1 and ribosomes (Frolova et al., 1996). ERF3 is essential for cell survival (Ter-Avanesyan et al., 1993). The human eRF3 is 138 amino acids long (Jean-Jean, LeGoff, & Philippe, et al., 1996) and therefore much shorter than prokaryotic RF3. In yeast eRF3 was first recognized as SUP35 (Kushnirov et al., 1988; Stansfield & Tuite, 1994), the omnipotent suppressor if damaged by mutation. In a similar manner, the yeast eRF1 was first recognized as SUP45 (Stansfield et al., 1995), which was later identified as RF1 by sequence homology with mammalian RF1 (Frolova et al., 1994).

eRF3 of yeast (Sup35 protein) is capable of propagating a specific conformation that gives rise to the [psi+] nonsense suppressor determinant (Wickner, 1994). This is due to the fact that eRF3 of yeast with [psi+] phenotype has prion-like characteristics. Sup35 protein (yeast eRF3) molecules interact with each other through their N-terminal domain in [psi+] but not in [psi–] cells (Patino, Liu, Glover, & Lindquist, 1996; Paushkin, Kushnirov, Smirnov, & Ter-Avanesyan, 1996). Thus, cells containing this form of eRF3 (Sup35p) show a depletion in the levels of soluble functional eRF3 that is sequestered in high–molecular weight, prion-like fibers. Though isogenic [psi+] and [psi–] strains show no difference in growth rates under normal laboratory conditions, [psi+] strains exhibit enhanced tolerance to heat and chemical stress, compared to [psi–] strains. Thus, the prion-like determinant [psi+] is able to regulate translation termination efficiency in response to environmental stress.

Ribosome Recycling

The termination step described in the preceding section leaves behind the ribosomal posttermination complex; the next step is disassembly of that complex. In *E. coli,* this process is catalyzed by two factors: elongation factor G (EF-G; Hirashima & Kaji, 1972, 1973) or RF3 (Grentzmann et al., 1998) and ribosome recycling factor (RRF, originally called ribosome releasing factor; Janosi, Shimizu, & Kaji, 1994). In addition to disassembly of the posttermination complex, RRF appears to help maintain translational fidelity during chain elongation (Janosi, Ricker, & Kaji, 1996). Discovered in 1970 (Hirashima & Kaji, 1970), RRF is present in every organism (Janosi, Hara, Zhang, & Kaji, 1996; Janosi, Ricker, & Kaji, 1996) and is essential (Janosi et al., 1994) for maintenance of life in all bacteria except archaebacteria (*Archaea:* Bult et al., 1996). *M. genitalium,* being the smallest free-living organism, with only 500 genes, manages without RF2 and RF3 (Fraser et al., 1995), but it retains RRF, suggesting the importance of RRF.

When RRF was omitted in the in vitro translation system, ribosomes remaining on the mRNA reinitiated unscheduled translation from the triplet next to the termination codon (Ryoji, Berland, & Kaji, 1981). Upon inactivation of RRF in vivo, a ribosome may frame-shift into all possible frames and may slide downstream as many as 10 to 45 nucleotides before it randomly starts translation of the mRNA (Janosi et al., 1998).

Eukaryotic RRF is an organelle protein (e.g., in chloroplasts or mitochondria) that is involved in protein synthesis within the organelles in much the same way bacterial RRF functions (Rolland et al., 1999). This conclusion is further supported by the fact that translation in chloroplasts is similar to that in prokaryotes (Danon, 1997; Harris, Boynton, & Gillham, 1994) and the fact that yeast (Kanai et al., 1998) and human (Zhang & Spremulli, 1998) RRF may be a mitochondrial protein. It should be noted that none of the Archeons contains RRF. Archeons, in between eukaroytes and prokaryotes in their phylogenetic development, have a protein synthesis system similar to that of eukaryotic cytoplasm. This suggests that the eukaryotic homologues of RRF are involved in the organelle protein synthesis but not in the cytoplasmic protein synthesis. This raises a question as to the factors responsible for the disassembly of the post-termination complex involved in the cytoplasmic protein synthesis in eukaryotes. This is an important question, which should be answered in near future. Four review articles on RRF have been published (Janosi, Hara, Zhang, & Kaji, 1996; Janosi, Ricker, & Kaji, 1996; Kaji & Hirokawa, 1999; Kaji, Teyssier, & Hirokawa, 1998).

RIGHT TO REFUSE TREATMENT

Past failures and current successes in the area of treatment have led to a paradoxical state of affairs: We involuntarily commit individuals for treatment, yet these very individuals frequently assert a right to refuse treatment.

Past failures regarding the hospitalized and involuntary patient have been well documented. Hospitalization per se, the therapeutic milieu of the hospital, and traditional talk therapy have not led to recovery, cure, and discharge rates. The patient rights movement, the right to treatment, and the right to treatment in the least restrictive setting have been endorsed by several courts and legislatures.

The legal roots of such a right to refuse derives from both common law, where, under tort law, informed consent is needed before medical or psychological treatments are initiated, and from constitutional law. Constitutionally, the first, fourth, eighth, and fourteenth amendments have been offered to establish such grounds.

The implications and questions, as well as dilemmas, for the continued treatment of involuntary patients are many, and the reactions of therapists are being heard. For one, is informed consent possible? Can an involuntarily hospitalized patient, who may have been institutionalized for many years, give competent, knowing, and voluntary consent? Might not the therapist be a double agent—also concerned with ward management or invested in a research project, as well as in the welfare of the patient? Are therapists not in a double bind—faced with suits for not treating and suits for treating? Will patients now be entrapped by both their psychoses and their rights? Will this lead to a challenge to psychology to develop nonmedical treatments that are both effective and consent worthy? At this stage, the questions and issues have surfaced far faster than the solutions.

RIGHT TO TREATMENT

In 1960 Morton Birnbaum, a physician and lawyer, proposed "The Right to Treatment." Although the Constitution does not speak directly about such a right or mention hospitalization, involuntary commitment, or treatment, Birnbaum reasoned that the eighth and fourteenth amendments, those dealing with cruel and unusual punishment and deprivation of liberty without due process and equal protection, could be construed to imply such a right. The issue is this: When states commit individuals to psychiatric hospitals on *parens patriae* grounds (i.e., because they are mentally ill and in need of treatment) or because they are incompetent to stand trial, is there not also the promise and obligation to provide treatment?

The first test case was *Rouse v. Cameron,* in which Judge Bazelon argued that such a right does exist. More recent cases bring to light the many complicated questions, issues, and implications facing the courts, communities, patients, mental health practitioners, legal advocates, and other branches of government.

The 1970s brought the revolution and litigation of patients' rights to the foreground; along with it have come a fresh examination of involuntary commitment procedures and hospital practices and the knowledge that our treatments have not fulfilled our promises.

RIGIDITY

Although the term *rigidity* has no precise definition, one offered by Chown (1959) comes closest to a working definition. Chown stated that rigidity describes behaviors that include the inability to change habits, sets, attitudes, and discriminations. Moreover, it can be said that rigidity is especially apparent when a person's behavior fails to change even though the demands of new situations require different behaviors.

Many terms in psychology refer to rigidity, including perseveration, conservatism, dogmatism, anality, intolerance of ambiguity, and compulsiveness. Terms such as flexibility, lability, tolerance of ambiguity, and, to some degree, creativity have served as labels for tendencies contrasted with rigidity. As Chown stated, these terms have been used rather loosely. Therefore, it is highly unlikely that rigidity is a single psychological construct or personality factor. However, it is valuable to examine some specific subtypes of rigidity in order to seek some common relationships among them.

Rigidity as Perseveration

In the *Abilities of Man,* Spearman (1927/1970) presented a law of inertia that stated that cognitive processes are slow both to start and to finish and then questioned whether there would be individual differences in inertia. Along these lines, Cattell (1935) isolated two factors of trait rigidity: *inertia,* in which the person is unable to switch between two well-established skills, and *dispositional rigidity,* which refers to the inability to apply an old skill to a new but different situation.

In his studies of neurological patients, Goldstein (1934/1959) noted that it was common to see patients who were unable to shift from one task to another. In addition, when faced with difficult tasks involving abstract thought, some patients would blurt out immediate but incorrect answers. In the 1940s, Goldstein and Scheerer (1941) developed a test battery that contained a variety of sorting and classification tasks. They found that individuals who had brain damage could often sort a group of objects according to one classification scheme (e.g., color) but would be unable to shift to another scheme (e.g., shape).

Goldstein believed that under ordinary circumstances, the healthy person functions as a whole system with well-integrated and articulated subsystems. However, with brain damage, the integrity of the system is destroyed, and the person is unable to handle the complexity required by abstract problems. Goldstein stated that the rigid, concrete behavior shown by patients with brain damage was not a simple deficit, but rather was an attempt to reduce complexity and to make a potentially overwhelming situation more manageable. Thus, Goldstein was able to link perseveration, brain injury, and concreteness into one pattern.

Laboratory studies conducted by Luchins (1942) and Maltzman and Morrisett (1953) indicated that when subjects were repeatedly presented with problem-solving tasks that at first had a fixed solution formula, they often rigidly continued to use the same solution formula for subsequent problems, even though these new tasks could be solved in a variety of ways. Although these authors attributed rigidity to task variables, other researchers were inspired to find individual differences in problem-solving perseveration by using these tasks and attempting to find correlations with measures of other ability and personality traits.

Intolerance of Ambiguity

A number of researchers and theoreticians, including T. W. Adorno, Else Frenkel-Brunswik, Milton Rokeach, Erich Fromm, David Shapiro, Stephen Breskin, Louis Primavera, and Bernard Gorman have noted a fairly consistent constellation of traits that includes strict obedience to authority figures, intolerance of opposing opinions, prejudice, a tendency to construct an oversimplified view of the world, a tendency to employ sharply polarized or black-white cognitive constructs, and a cynical view of human nature. Numerous studies have indicated that this constellation is not limited to rigid social and political beliefs alone but extends to many laboratory tasks as well.

The development of such authoritarian and dogmatic personality patterns has been attributed to socialization practices that include blind, unquestioning obedience to parents and other authority figures and discipline practices that emphasize power and coercion, rather than reasoning, induction, and explanations of personal moral choices. Therefore, the rigid person has been constantly exposed to situations that state that there are absolute rules to be followed and that deviations from such rules will be met with severe punishment.

Discussions of rigid, authoritarian, and dogmatic belief systems have been extended to psychopathology. Clinically, highly dogmatic and rigid behaviors can be observed in obsessive-compulsive and paranoid patients. Such patients' thoughts and actions are replete with examples of logical contradictions, rigid and overselective constructions of situations, and complaints of being driven to perform certain actions.

In *Neurotic Styles* (1965) and in *Autonomy and Rigid Character* (1981), Shapiro explored a paradox in these disorders; namely, that although patients claim to be rigidly following and driven by principles seen as alien to their selves, people consciously plan and execute behaviors instrumental in supporting these beliefs. Shapiro reconciled this paradox by noting that the mandated shoulds and oughts are the beliefs of important authority figures. Although the rigid person does not desire to carry out these demands, he or she feels powerless to disobey them. For example, an obsessive patient may know that it is useless to worry but also believes that a display of conscientiousness to others is the proper thing to do. Thus, the person is

placed in a conflict between beliefs about his or her own lack of personal efficiency and the presumed power of others over the self.

An Integration of Approaches

How can observations that rigid people display perseveration, concreteness, intolerance of ambiguity, and avowals of authority-centered beliefs be subsumed under a single term? Perhaps an explanation may be found by using Jean Piaget's theory of cognitive development.

Throughout his many writings, Piaget had shown how new cognitive schemes develop through the clash of two opposite adaptive tendencies: assimilation (the tendency to fit new knowledge into existing schemes) and accommodation (the tendency to modify behavior according to the demands of the situation). Either tendency alone could be properly considered to be rigidity. However, through situations in which assimilation is checked by accommodation, and vice versa, new and more flexible equilibrated schemes are formed (Piaget, 1968).

Piaget had shown how early thought is characterized by overassimilation and overaccommodation and cogently demonstrated that young children and adults with mental retardation employ one-dimensional, rigid, "centered" cognitive strategies in comparison with the multidimensional, flexible, "decentered" strategies employed by older children and normal adults. According to Piaget, affective and moral development is inseparable from cognitive development. Therefore, the rigid behaviors found in intellectual tasks have their parallels in the lack of autonomy, the perseveration, and the rigid constructions of personal and interpersonal values found in social behaviors.

It may be that rigidity, in both the intellectual and affective domains, is a manifestation of unbalanced schemes in which either accommodation or assimilation predominates. As many factors, including cognitive immaturity, neurological damage, and authority-oriented child-rearing practices, may hinder the development of adequately equilibrated schemes, rigidity may stem from many different roots.

RITUAL BEHAVIOR

Ritual is a conventionalized joint activity that is given to ceremony, involves two or more persons, is endowed with special emotion and often sacred meaning, is focused around a clearly defined set of social objects, and when performed, confers upon its participants a special sense of the sacred and the out-of-the-ordinary (Denzin, 1974, p. 272). When a ritual is performed, ritual participants through their actions convey their respect to themselves to "some object of ultimate value . . . or to its stand-in" (Goffman, 1971, p. 62). A ritual consists of interrelated activities and acts, termed *rites,* and is performed within sacred or special interactional situations, termed *ritual settings.* Ritual performances legitimize the selves of the ritual performers and solidify their standing within a social relationship's

or a social order's hierarchy of morality. Ritual may grow out of any sector of group life, including sexual, economic, political, religious, legal, and interpersonal arenas of discourse and interaction (Douglas, 1975, pp. 60–61). Rituals permit few variations and are subject to the pressures of interactional normalization. They have the features of drama and involve the reenactment of cultural and world views held to be salient and central by human groups (Geertz, 1973; Harrison, 1912). Modifying Bateson (1972) slightly, one may say that *ritual* is the name of a frame for action, and within the frame of ritual, individuals act ritualistically.

Durkheim (1912) divided ritual into two categories: positive and negative, or sacred and profane. Positive rituals bring interactants together in ways that support their social relationship and permit offerings of various kinds, including the giving of gifts and greetings (Goffman, 1971). Negative or avoidance rituals, commonly termed taboos, protect the individuals and their properties from the intrusions of others.

Religious rituals, in contrast to interpersonal rituals, are the rules of conduct that prescribe how a person should comport him- or herself "in the presence of . . . sacred objects" (Durkheim, 1912, p. 41). Interpersonal rituals are "brief rituals one individual performs for and to another, attesting to civility and good will on the performer's part and to the recipient's possession of a small patrimony of sacredness" (Goffman, 1971, p. 63). According to many observers, including Goffman, interpersonal rituals have replaced sacred rituals in contemporary Western societies. A confusion over interpersonal, religious, and cultural rituals characterizes many of the developing nations of the world today (Geertz, 1973).

Rituals may be performed, as Malinowski (1913), Radcliffe-Brown (1922), Frazer (1890), Smith (1889), Durkheim (1912), Levi-Strauss (1962), van Gennep (1909), and Warner (1962) have argued, for purely magical, mystical, or religious reasons; so as to mark or gain some control over the uncontrollable, often occurrences in the natural world; transgressions of the group's moral code; or the existential certainties of birth, death, and the life cycle transitions from status position to status position within the group's social structure (e.g., child to adult, male to husband and father, female to wife and mother, etc.). Rituals are also enacted for the emotional effects the performance bestows on individuals. Participation may be voluntary or obligatory, large or small in numbers of participants, and negative or positive in tone, and often it will be connected to sacred (religious) and secular (political and interpersonal) calendars (Warner, 1962).

Ritual performances require the organization and focusing of ritual acts around stand-in objects whose presence is required for the ritual to be accomplished. These objects include, at a minimum, actors (performers and audiences), settings or stages for the ritual performance, a class of previously selected objects to be acted on during the occasion of ritual display, and a script, or prearranged interactional text, that will be followed, spoken, and enacted. Stand-in objects may include wedding rings, hymns, music, food, drink, and talk. The meanings of the ritual derive from the actions that persons direct toward these stand-in objects and toward themselves.

Serial ritual display characterizes ritual performances. In no sense can a ritual be accomplished all at once; it must proceed through phases, which are scheduled, interconnected, and made up of sequences of small ritual acts or rites. Ritual meals (Douglas, 1975) display this feature of serial ritual display. The social organization of ritual activities, in terms of serial ritual display, reveals the underlying power and control hierarchies in a group's social structure (Leach, 1968).

Social Relationships and Ritual

Social anthropologists, sociologists, and social psychologists "claim that their special field is the study of social relationships" (Leach, 1968, p. 524). While social relationships cannot be studied directly, the interactions that occur between individuals can be, and to the extent that these interactions are ritualized and conventionalized, ritual becomes a principal means for studying social relationships. Goffman's (1971) analysis of supportive and remedial interchanges, rituals of ratification, access, and departure in interpersonal rituals suggests that rituals serve to separate and join persons simultaneously. Greetings, for instance, maintain distance between persons, while joining them, if only momentarily, in a shared interactional exchange.

Perhaps more important than this joining and separating feature of rituals in social relationships is the fact that they have meaning only within the context of social relationships. That is, in social relationships, persons find and confirm their identities, and in these relationships, they join their actions to the ongoing fabric of the social life of their group. Rituals become one of several avenues (others include routines and problematic acts) for bridging the gap between persons and the social order, and provide a salient bond for connecting persons to one another.

At a deeper relational level, it can be argued that persons are connected to their societies through ritual ties. Thus ceremonies such as the coronation of the queen in England are seen by Shils and Young (1953) as instances of national communion in which ordinary, everyday individuals are drawn together into the moral fabric of their society. The queen and her coronation ritually embody all that being English entails and means. Participation in the ritual by members of the audience symbolically accomplishes a joining of the person with the society. It is a paradox that the rituals that stand nearest to the core of a society (coronations, inaugurations, etc.) are most typically at the society's most distant, peripheral interpersonal edges. Thus, core interpersonal rituals of the person and the group often

stand in contradistinction to the core, sacred values and rituals of society at large (Shils, 1976).

Ritual as Interaction

Ritual must be understood as interaction, and not in static, strictly structural terms. While rituals do, in the abstract, stand outside and above persons, their lived meaning resides in the world of face-to-face interaction wherein they are acted on, defined, produced, and interpreted. When a number of persons join hands around a table and begin reciting the Lord's Prayer in unison, they are interactionally, collectively, and conjointly engaging in a shared ritual activity. With eyes closed, left hand clasping the extended right hand of the person to the left, right hand clasping the left hand of the person to the right, they, individually and interactionally, join and offer their presence to the collective presence of the group. Their voices are embodiments of their physical presence and participation in the ritual. Each individual is a part of the ritual, just as the ritual becomes a part of each person. The interactional accomplishment of a ritual requires individual and collective participation; but most important, it requires interaction. Ritual, then, is symbolic interaction, and should be studied as such (see Blumer, 1969).

Alternative Views of Ritual

The foregoing suggests that the meaning of ritual lies in interaction, not in rituals per se or in abstract structures. There are, however, alternative ways of formulating ritual. Rituals may be studied semiotically and structurally, in terms of the binary oppositions that constitute the inner or primary text of the ritual (Barthes, 1967; Levi-Strauss, 1962, 1963). Thus, paired oppositions within rituals and myths (male-female, life-death, near-far, old-young, etc.) may be examined and fitted together within a structural totality.

Rituals may be studied dramaturgically and their symbolic and cultural contents may be given special attention. Rituals may be studied in terms of the power they are intended to produce, just as they may be conceptualized as beliefs in illusion or in myth, magic, or religion. However, when ritual action transforms people's relationships to themselves, to others, and to their environment, more than the belief in an illusion is involved. Rituals and the actions they entail are real and consequential in their interactional implications, especially when the meanings of the ritual carry over into other sectors of the group's and the individuals' lives.

Conclusions

The import of ritual in everyday life may be summarized in terms of the following three assertions:

1. That which a group takes to be problematic will be subjected to pressures to make those problematic objects, acts, and events predictable and routine. This is necessary if orderly actions are to be taken toward them.
2. Groups and relationships display constant negotiated struggles over what is problematic, routine, and predictable.
3. At the heart of organized group life lies a complex network of rituals—interpersonal, positive, negative, sacred, and secular—that are communicated to newcomers to the group and that, when taught and successfully performed, lead to systematic ways of making everyday group life predictable, ordinary, and taken for granted.

An understanding of the everyday, taken-for-granted features of group life requires the systematic study of ritual. The understanding of how persons are connected to others and to the society at large demands similar study. Rituals stand at the intersection of the individual and society and require detailed examination by the disciplines of social anthropology, sociology, social psychology, psychology, religion, and philosophy. Indeed, Rosaldo (1993) suggests that ritual is best viewed as a busy intersection, as a place where a number of distinct and important cultural processes intersect. The notion of ritual as a busy intersection anticipates the more contemporary view of culture as a complex, ongoing process. In this view culture is not a self-contained whole made up of coherent, stable, unchanging patterns and rituals (Rosaldo, 1993).

ROSENZWEIG PICTURE-FRUSTRATION (P-F) STUDY

The Rosenzweig Picture-Frustration (P-F) study is a semi-projective technique of personality diagnosis that has been

successfully used for the past half-century both as a clinical device and as an investigative procedure. It was developed as a method for exploring concepts of frustration theory and examining some dimensions of projective methodology (Rosenzweig, 1945). Based on earlier experiments on psychodynamic concepts, including frustration, repression, and directions and types of aggression, an Adult Form appeared in 1948. A Children's Form for ages 4 to 13 was published four years later, and in 1964 a form for Adolescents was added.

The P-F consists of a series of 24 cartoon-like pictures, each depicting two persons involved in mildly frustrating situations of common occurrence. Facial features and other expressions of emotion are deliberately omitted from the pictures. The figure at the left is always shown saying words that help to describe the frustration of the other individual. In the blank caption box above the frustrated figure on the right, the subject is asked to write the first reply that enters his or her mind.

It is assumed as a basis for P-F scoring that the examinee unconsciously or consciously identifies with the frustrated individual in each picture and projects his or her own bias into the responses given. To define this bias, scores are assigned to each response under two main dimensions: direction of aggression and type of aggression. Direction of aggression includes extraggression (EA), in which aggression is turned onto the environment; intraggression (IA), in which it is turned by the subject onto him- or herself; and imaggression (MA), in which aggression is evaded in an attempt to gloss over the frustration. It is as if extraggressiveness turns aggression *out,* intraggressiveness turns it *in,* and imaggressiveness turns it *off.* Type of aggression includes obstacle-dominance (OD), in which the barrier occasioning the frustration stands out in the response; ego (etho) defense (ED), in which the ego of the subject predominates to defend itself, and need-persistence (NP), in which the solution of the frustrating problem is emphasized by pursuing the goal despite the obstacle. From the combination of these six categories, there result for each item nine possible scoring factors.

It is essential to observe that aggression in the P-F and in the construct on which it is based in not necessarily negative in implication. In the context of the P-F, aggression is generically defined as assertiveness, which may be either affirmative or negative in character. Need-persistence represents a constructive (sometimes creative) form of aggression, whereas ego (ethos) defense is frequently destructive (of others or of oneself) in import. This point is particularly noteworthy because in many technical theories of aggression this distinction is overlooked and aggression is thought to be practically synonymous with hostility or destructiveness. Common parlance, when not contaminated by psychoanalytic or other psychological conceptualizations comes close to the broader usage of the term *aggression,* which the P-F Study employs.

Although the scoring of the P-F is always phenotypic (according to the explicit wording used in the response), interpretation is genotypic, involving three kinds of norms: universal (nomothetic), group (demographic), and individual (idiodynamic). Statistical data used in interpretation refer to group norms, that is, the extent to which the individual performs vis-à-vis the group to which he or she belongs (based on age, sex, etc.). Individual (idiodynamic) norms, which derive from the unique wording of the responses and in interrelation of the scored factors in the protocol, complement the group norms. Universal (nomothetic) norms are represented by the constructs on which the instrument is based, and these underlie both group and individual norms. A Group Conformity Rating (GCR) measures the subject's tendency to agree with the modal responses of a normal population sample.

Interscorer reliability has been found to be 85% for the adult form. The results of a retest reliability, with some variations, have been demonstrated to be high. The various scoring categories selectively showed significant reliability as determined by the split-half method, but by the retest method the major scoring dimensions of the P-F have been demonstrated to agree with significant reliability.

The P-F has been studied for both construct (criterion-related) and pragmatic validity with significantly positive results. In addition to the clinical purposes for which the P-F study was originally intended, it has been used as a screening or selection device in business, industry, and schools and for research on cultural differences. In particular, the GCR has proved to be of value. The categories of "etho-defense" and "need-persistence" also have been shown to have differentiating potential, and some positive results have been obtained for obstacle-dominance. The results of P-F in hospital and clinic settings have proved useful, but an exclusive reliance on the P-F as a symptom-differentiating tool in such contexts is not recommended. Used in conjunction with other tests or as part of a configuration index, the technique has significant potential.

The published evidence for P-F reliability and validity are summarized in the *Basic Manual* (Rosenzweig, 1978b) and discussed in detail in the book *Aggressive Behavior and the Rosenzweig Picture-Frustration Study* (Rosenzweig, 1978a).

It is important to observe that the P-F Study is one of the few projective methods that directly apply a systematic theory of behavior, in this case, of aggression. Moreover, by employing in its scoring the three types of norms (nomothetic, demographic, and idiodynamic), the instrument is compatible with the general theory of personality known as idiodynamics.

The P-F has been translated and adapted, with standardization, in nearly all the countries of the Americas, Europe, and Asia and thus has become a natural tool for cross-cultural investigation. It is particularly noteworthy that the Japanese have intensively pursued the relationship be-

tween the constructs of frustration theory and the standpoint of idiodynamics, and a Japanese book on this topic is in preparation.

RUSSIAN NEUROPSYCHOLOGY AFTER LURIA

Now, when the psychologists all over the world have commemorated the centennial anniversary of the birth of A. R. Luria (1902–1977), we can realize his continuous enormous influence to different branches of Russian neuropsychology.

The Problem of Interhemispheric Specialization and Interaction

Research has revealed interhemispheric specialization for different forms of memory (Korsakova & Mikadze, 1982; Simernitskaya, 1978) as well as greater vulnerability of the right hemisphere to cerebral pathology and lower compensating capabilities (Vasserman & Lassan, 1989). The right hemisphere was proved slower in information processing than the left one (Krotkova, Karaseva, Moskovichyute, 1982) and less able to regulate and accelerate mental activity (Homskaya, Efimova, Budyka, & Enikolopova, 1997). It was also shown that each hemisphere is specific for different types of reasoning such as empirical or logical reasoning as well as for intensity and stability of human emotions, and there are unilaterally and bilaterally realized functions, or a competence of each hemisphere (Homskaya & Batova, 1998; Meerson & Dobrovolskaya, 1998). Each mental activity is realized through the interaction of both hemispheres, each making a specific contribution. New evidence proves that interhemispheric differences can be revealed both on cortical and subcortical levels. Cognitive defects specific for the left hemisphere are more evident in cortical lesions, whereas subdominant syndromes appear predominantly after subcortical lesions of the right hemisphere (Moskovichyute, 1998).

Subcortical Brain Pathology

A good model for studying cognitive disturbances due to subcortical damages is Parkinson's disease (PD; Glozman, 1999b; Korsakova & Moskovichyute, 1985). The pattern of cognitive disturbances in persons with PD is a specific combination of natural brain alterations appearing with age

and specific impairments caused by the disease. This pattern is not the sum of both components but a qualitatively new complex of symptoms. Quantitative and qualitative integration of Lurian procedures was proved necessary to reveal these data (Glozman, 1999a).

Dementia should not be considered as an obligatory component of PD, and it is not limited to the symptoms of so-called subcortical dementia. It includes some cortical cognitive disorders, the pattern of which is different from that of Alzheimer's disease (AD).

Neuropsychology of Older Persons

Luria's (1973) conception of three functional units of the brain may help to differentiate normal and abnormal aging (Glozman, 1999b; Korsakova, 1998). In the normal elderly, the functioning of the first unit—that of activation—is predominantly disturbed, and this is manifested in general slowness, aspontaneity in all activities, increased inhibition of memorized information by interfering stimuli, and restriction of the volume of mental activities when different programs must be simultaneously retained and realized. The normal aging represents a stage of individual development, necessitating a change in strategies, voluntary selection and use of new forms of mediating mental activity. In pathological atrophic states, such as AD or senile dementia, not only these symptoms are aggravated, but defects in functioning of the two other cerebral units are also demonstrated. Progression of cognitive disturbances leading to the appearance of vascular dementia is predominantly due to regulatory and operational deficits connected to cortical brain regions. A corticalization of the cognitive and executive disturbances thus occurs. The evolution of AD is realized by the consecutive frontalization and subcorticalization of impairments, that is, by superimposed neurodynamic and regulatory impairments upon operational ones.

Developmental Neuropsychology

The further growth of developmental neuropsychology in Russia follows two main lines: study of individual features during the development of cognitive functions (Akhutina, 1998, 2001; Mikadze & Korsakova, 1994) and analysis of interhemispheric interaction in abnormal development (Semenovich, 2002).

Neuropsychological diagnosis of causes responsible for learning problems revealed heterogeneity in the maturation of brain structures and connections in the development of functional systems and significance of a correspondence between the child's abilities and exigencies of the learning programs. The emphasis of the assessments is a modification from diagnostic evaluation to prognostic and corrective suggestions. The neuropsychological assessment should emphasize the subject's strengths, which are important in his or her correction (rehabilitation) program and predict his or her ultimate integration into society. This principle was first realized in aphasiology as the so-called socio-psychological aspect of rehabilitation (Tsvetkova, 1985; Tsvetkova et al., 1979) and then in studies of interrelations between communication disorders and personality in different nosological groups (Glozman, 2002) and in developmental neuropsychology.

Neuropsychology of Individual Differences

Neuropsychology of individual differences is an application of neuropsychological concepts and methods to the assessment of healthy subjects that tries to explain normal functioning by using principles of cerebral organization, particularly characteristics of interhemispheric asymmetry (motor, acoustic, and visual) and interhemispheric interaction (Homskaya & Batova, 1998; Homskaya et al., 1997). The authors identified 27 possible profiles of lateral brain organization and their correlation to aspects of cognitive, motor, and emotional activity of the normal subjects, as well as their adaptive abilities.

To summarize, three main trends can be seen in the development of neuropsychology in the former Soviet Union:

1. Extensive further expansion of research and practice, that is, embracing numerous new domains and nosological patient groups
2. Combination of qualitative and quantitative approaches
3. A social and personality-based orientation

S

SADISM

The origin of the term *sadism* is associated with the Marquis de Sade, a French writer (1740–1815). He wrote novels in which he describes scenes of torture and killing in a sexual context (Hucker, 1997). In the *DSM-IV* (American Psychiatric Association [ApA], 1994), sadism is defined as a paraphilia and is included in the section on sexual and gender identity disorders. A diagnosis of sadism requires the following criteria: "over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving acts (real, not simulated) in which the psychological or physical suffering (including humiliation) of the victim is sexually exciting to the person" and "the fantasies, sexual urges, or behaviors cause clinically significant distress or impairment in social, occupational or other important areas of functioning" (ApA, 1994, p. 530). According to Dietz, Hazelwood, and Warren (1990), the essence of sadism is not the suffering of the victim but the complete power over the victim; in fact, "there is no greater power over another person than that of inflicting pain on her" (p. 165).

Sexual sadism may be expressed in fantasies only, in sexual behaviors with a consenting partner (e.g., bondage, mild torture) or in sexual aggressions (e.g., rape, sexual murder). The incidence of sadistic fantasies such as humiliating a woman (14.9%) or beating up a woman (10.7%) is not infrequent among men in the general population (Crépault & Couture, 1980). In addition, 5% of males and 2% of females obtained sexual gratification from inflicting pain in mutually consenting sexual activities (Hunt, 1974). Finally, a significant proportion of sexual aggressors and sexual murderers of women acted out sadistic behaviors during their offences (Groth & Birnbaum, 1979; Knight & Prentky, 1990; Ressler, Burgess, & Douglas, 1988).

The childhood and adolescence of sexually sadistic criminals are characterized by a blend of violence, sex, and social isolation. A number of sexually sadistic criminals have an ambivalent relationship (love/hate) with their mothers. In addition, a number of sexually sadistic criminals reported that they were physically victimized by an authoritarian father. Following these inadequate interactions with their parents, they developed an inadequate attachment style characterized by a withdrawn attitude and social isolation (Brittain, 1970). During adolescence, they developed a low self-esteem due to failures in social and sexual interactions. Then, deviant sexual fantasies and paraphilic behaviors (e.g., exhibitionism, voyeurism, fetishism) became their main source of emotional stimulation and gratification (MacCulloch, Snowden, Wood, & Mills, 1983). Deviant sexual fantasies become sadistic in order to maintain a high level of sexual arousal.

Adult sexually sadistic criminals are introverted, shy, and socially inept and isolated. They rarely show violence, but they have an interest in guns and detective magazines (Brittain, 1970). In addition, they often establish a reputation as a solid citizen (Dietz et al., 1990). Finally, they have a rich fantasy life and are engaged in a diversity of paraphilic behaviors (Gratzer & Bradford, 1995).

Regarding their personality, sexually sadistic criminals are usually described as psychopathic and narcissistic (Dietz et al., 1990). Such a diagnosis is congruent with their lack of empathy during their crimes and with their view of themselves as supercriminals. However, their usual way of relating to others is instead characterized by avoidant (e.g., low self-esteem) and schizoid (e.g., withdrawn) personality disorder traits (Proulx, 2001).

The criminal offences of sexual sadists are well planned and organized (Ressler et al., 1988). They choose an unknown victim who is taken to a place selected in advance. Often, the victim is kept in captivity for more than 24 hours (Dietz et al., 1990). During the crime, the victim is tortured and humiliated (Grubin, 1994). Frequently, foreign objects are inserted into the victim's vagina or anus (Warren, Hazelwood, & Dietz, 1996). Finally, the victim is usually killed by strangulation (Brittain, 1970).

After the crime, sexual sadists behave normally until their next offense (Podolsky, 1965). They report no guilt or remorse. They usually feel a great relief of tension after the crime. Finally, they may consider that they are superior to the police because they avoid detection. In fact, as suggested by Brittain (1970), a sexual sadist "may feel himself to be inferior, except as regard to his offence" (p. 199).

SADISTIC RITUAL ABUSE

Sadistic ritual abuse (SRA; Goodwin, 1992), also known as satanic ritual abuse or ritual abuse has been defined as a "method of control of people of all ages consisting of physical, sexual, and psychological mistreatment through the use of rituals" (Rhoades, 1999, p. 844).

Levels and Symbols of Satanism

Satanism has been defined in four levels (Simandl, 1997): (1) the experimental-dabbler, typically a teenager; (2) nontraditional, self-styled satanists, individuals or small groups obsessed with satanic themes; (3) organized traditional satanists, organized religious groups that are protected by religious freedom under American law, such as the Church of Satan; and (4) occultic networking or transgenerational cults, SRA groups perpetuated through family generations and the focus of this article (Ryder, 1992).

Commonly reported satanic symbols (Pulling, 1989) include the pentagram, inverted pentagram, hexagram (Star of David), cross of Nero (peace symbol or broken cross), swastika, anarchy symbol, thaumaturgic triangle, udjat (all-seeing eye), scarab, lightning bolts, the number 666, ankh, inverted cross, black mass indicator, an emblem of Baphomet, the symbol of the Church of Satan, and the cross of confusion.

The SRA Controversy

The Satan Seller (Warnke, 1972) and *Michelle Remembers* (Smith & Pazder, 1980) introduced SRA to public awareness. The FBI first received reports of possible SRA activity in 1983 (Lanning, 1991). The initial explosion of interest in and controversy surrounding SRA in Christian (Passantino & Passantino, 1992), professional (Mulhern, 1992; Putnam, 1991), and law enforcement circles (Hicks, 1991; Lanning, 1989) was soon supplanted by the controversy over "recovered memory" and the "backlash" (Myers, 1992) against reported survivors of sexual abuse and their therapists. In 1998, the potential legal suits against mental health professionals were estimated to be in the thousands (Brown, Scheflin, & Hammond, 1998).

More books than journal articles have been written on SRA, including reported survivors (Ryder, 1992), a parent accused of sexual abuse (Pendergrast, 1995), journalists (Nathan & Snedeker, 1995), researchers (Loftus & Ketcham, 1994), therapists (Fraser, 1997; Ross, 1995; Sakheim & Devine, 1992; Yapko, 1994), fictionalized accounts of SRA (James, 1994; Larson, 1991), and children's books on SRA (Sanford, 1990).

The basic controversy is over whether such cults exist, and if they do exist, how they are organized and how they conspire to abuse people (Sakheim & Devine, 1992). Alternative explanations for SRA allegations include pathological distortion; traumatic memory; normal childhood fears and fantasy; and misperception, confusion, and trickery by perpetrators (Lanning, 1992); overzealous interveners (Ganaway, 1992); contaminating effects from the media, society, parents, and professionals (Ganaway, 1989; Jones, 1991); a social delusion (Mulhern, 1994); a moral panic (Victor, 1998); SRA training seminars (Mulhern, 1992); and "misdiagnosis, and the misapplication of hypnosis, dreamwork, or regressive therapies" (Coons, 1994).

Research with the Word Association Test (WAT; Leavitt & Labott, 1998; also Leavitt, 1998) and Rorschach (Leavitt & Labott, 2000) suggested that an experience base was shared by individuals reporting SRA that was not found in individuals who did not report satanic abuse (even if they

did report sexual abuse). The increased production of satanic word associations was not found to be associated with high hospital or media exposure.

The SRA controversy broadened with the recovered memory debate and the formation of the False Memory Syndrome Foundation (Goldstein, 1992). A number of states amended their statutes of limitations to grant delayed discovery, wherein adult survivors of childhood sexual abuse could sue their reported abusers (Crnich & Crnich, 1992). Five states (Louisiana, Missouri, Texas, Idaho, and Illinois) have passed laws addressing the ritual abuse of children (Simandl, 1997). Ritual abuse prosecutions (Tate, 1994) and research by therapists (Jonker & Jonker-Bakker, 1991; van der Hart, Boon, Jansen, 1997) in Europe have shown that SRA is not just a North American phenomenon.

Ritual Abuse of Children

Snow and Sorensen (1990) conducted a study of ritualistic child abuse in five separate neighborhood settings. They discovered that in four out of five neighborhoods, three distinct components of the sexual abuse appeared: incest, juvenile perpetration, and the adult ritual sex ring.

Finkelhor and Williams (1988) conducted a 3-year study of sexual abuse in day care centers in America and noted that 13% of the cases involved ritualistic abuse. Kelly (1989) found that the ritualistically abused children experienced significantly more types of sexual abuse, severe physical abuse, and threats of being watched by Satan.

Child Therapeutic Issues

Gould (1992) noted that the three factors of drugs, hypnosis, and intolerable abuse leading to dissociation, combined with the ritualistic abuse of children, before the age of 6 often create "amnesic barriers," making spontaneous disclosure of abuse unlikely.

Gould (1992) developed a twelve-category checklist for signs and symptoms of ritualistic abuse in children. Therapy involved play therapy with the gradual disclosure of the abuse to the therapist and nonabusive parents (Gould, 1992). The therapist was to be active in the treatment in structuring the therapeutic activities and providing motivation to the child to address issues that otherwise the child may avoid, including possible multiplicity and mind-control programs (Gould & Cozolino, 1992). Treatment is typically done in three stages (Herman, 1992), such as engagement, the trauma work, and resolution (Waters & Silberg, 1996), addressing the five domains (Silberg, 1996) of cognitive, affective, physical, interpersonal, and spiritual.

Ritual Abuse of Adolescents

Tennant-Clark, Fritz, and Beauvais (1989) noted a psychosocial profile of high occult participants in adolescents: chemical substance abuse, low self-esteem, negative feelings about school, poor self-concept, low desire to be considered a good person, negative feelings about religion, high tolerance for deviance, negative feelings about the future, low social sanctions against drug use, and feeling blamed (p. 768). Simandl (1997) saw these teens as having an undue fascination with death, torture, and suicide; alienation from family and religion; drastic change in grades; and a "compulsive interest in occult material, fantasy role games, and films and videos (all with themes of death, torture, and suicide)" (pp. 216–217).

Adult Survivors of Childhood Ritual Abuse

Young, Sachs, Braun, and Watkins (1991) reported a study of 37 adult patients with dissociative disorder who reported ritual abuse as children. All reported abusive rituals during satanic worship. The types of abuses reported were, in order of decreasing percents, sexual, witnessing and receiving physical pain or torture, witnessing animal mutilation or killings, death threats, forced drug usage, witnessing and forced participation in human adult and infant sacrifice, forced cannibalism, marriage to Satan, buried alive in coffins or graves, forced impregnation, and sacrifice of one's own child.

Adult Therapeutic Considerations

Clinical presentations are often dissociative (Leavitt, 1994) and posttraumatic stress disorder symptoms, in addition to "cult-related phenomena, bizarre self-abuse, and unremitting eating, sleep, and anxiety disorders" (Young & Young, 1997, p. 69). Treatment would thus involve principles and techniques that have been found to be effective with posttraumatic stress disorder and dissociative disorders (Kluft, 1985; Putnam, 1989, 1997; Silberg, 1996; van der Kolk, 1987; van der Kolk, McFarlane, & Weisaeth, 1996; Whitfield, 1995).

Treatment typically involves the three stages of safety-stability, trauma work, and integration (Herman, 1992; Rhoades, 1995a), while taking precautions to help prevent false memory allegations (Rhoades, 1995a, 1995b, 1995c). Treatment methods include abreaction; hypnosis; expressive therapies such as journaling, art, and sand tray; medication; hospitalization, including voluntary restraints (Young, 1992; van der Kolk, 1987; van der Kolk, McFarlane, & Weisaeth, 1996) and 12-step groups as an adjunct to therapy (Shaffer & Cozolino, 1992).

SADNESS

Until recently, the study of emotion was primarily left to novelists and poets, who have provided some of the most poignant analyses of emotions such as sadness, whether from the Bible—"They that sow in tears shall reap in joy" (Psalms)—or from Shakespeare:

> Give sorrow words. The grief that does not speak
> Whispers the o're fraught heart, and bids it break. (*Macbeth*)

Psychology had ignored the challenges laid down in Charles Darwin's famous study of emotion, *The Expression of the Emotions in Man and Animals* (published in 1872) and in earlier philosophical analyses by Descartes, Plato, and Aristotle. However, the past few decades have seen an exponential increase in interest in the study of emotion.

Sadness, like other emotions, is easy to experience or recall yet hard to describe or define. The main reason is that emotions are complex, multilevel states that include a number of important elements; namely, important external or internal events that typically lead to sadness, an interpretation and appraisal of the significance of those events, a physiological state characteristic of the emotion, a state of readiness to act in a way appropriate to the emotion, the possible conscious awareness of the emotion state, and overt behavior. In addition, these states are experienced in important social and cultural contexts, which may have complex rules about expression, suppression, or transformation of the emotions. Some of these points are elaborated in the following.

The most characteristic focus in sadness tends to be on events that include loss or failure, either real or imagined, in the past, the present, or the future. There is an appraisal of loss or failure, in which the lost object or goal varies in degree of importance and type; it could be a person, a place, an ambition that has not been attained, an object of personal value (e.g., a special pen, an important gift), or a loss of an ideal or moral value. The focus of sadness is therefore on the appraisal of loss of one or more goals across one or more domains. The loss need not be permanent but could be a temporary separation from a loved one or a loved place or even sadness experienced at the return to a loved one or a loved place following a period of separation. Moreover, the focus of the loss may be on a significant other rather than oneself, for example, one's child's failing an exam or being ill or injured. Indeed, the loss may be communal rather than personal, as in the loss of a head of state, a favorite film star, or failure by one's national team in the World Cup. Although sadness is typically classified as a negative emotion, there are many types of sadnesses that are experienced positively, such as sadness following a film or novel or the bitter-sweet combination of sadness and happiness experienced in nostalgia.

One of the dominant approaches within psychology to the study of emotions such as sadness is that of the basic

emotions approach. This approach follows in the traditions of Descartes and Darwin and emphasizes the possibility that there is a limited set of innate emotions that occurs universally across all cultures and from which other more complex emotions are derived. One of the major exponents of the basic emotions approach has been Paul Ekman, who has shown that facial expressions of emotions such as sadness are recognized and experienced across a wide range of cultures. Although there is no clear agreement as yet about the exact number of basic emotions, the emotions of sadness, anger, anxiety, disgust, and happiness would be on most emotion theorists' lists of basic emotions. However, the approach is not without its critics, both from within psychology and from other areas such as anthropology, where the issue of cultural relativity versus universality has been keenly debated for a wide range of psychological and social functions. All involved in the debates agree that the *expression* of emotions, especially in adults, varies considerably across individuals and cultures both currently and historically. In fact, sadness provides some of the best examples of this variation; thus, in different times and places it has been seen as anything varying from a weak, "feminine," negative emotion leading to a loss of status for males to that of a highly desirable aesthetic state connected with high creativity (e.g., in Elizabethan England) or a state leading to compassion for others (e.g., in Catherine Lutz's study of the Ifaluk Islanders).

The modern approaches to emotion are also characterized by an emphasis on the function of emotion and reject the long-dominant Platonic view that emotions are the antithesis of reason and that they are simply disruptive of normal functioning. In the case of sadness, the functions seem to range from a period of reflective self-examination in which current goals and relationships are reexamined and reevaluated (emphasized more in individualistic Western cultures) to the seeking of help from others or offering of help to others (emphasized in the more collectivist Eastern cultures). In the infant, cries of distress early on develop into sadness by about 3 months of age with a characteristic facial expression, crying, and tears. Tears (i.e., other than as a reflex for lubrication of the eye) as part of the expression of emotion are uniquely human and illustrate the importance of the social signaling function of the face. They do not, however, occur only in sadness but can appear also with, for example, joy or laughter; as with sadness, they are an expression of the intensity of the emotion experienced.

Finally, the basic emotions approach emphasizes that a range of more complex emotions is derived from sadness because of an increase in the intensity of the emotion, because of the different circumstances in which the emotion can be experienced, or because of the combination or blending of sadness with other basic emotions. The more extreme variants of sadness seen in grief, bereavement, and mourning or in disorders derived from sadness such as depression have been widely studied in psychology, whereas the milder, everyday variants have received little attention. The experience of extreme grief consequent on the loss of an attachment figure can be seen as the major loss of mutual goals, roles, and plans that the loss of attachment figures entails. Because of the evolutionary base to attachment, the universal experience of grief across cultures must in part have an innate basis and is likely therefore to involve the operation of an automatic or unconscious route to emotion. It has been suggested that the focus on the extreme and the abnormal may perhaps represent something of our own cultural problems with sadness and its expression, especially in these extreme circumstances.

SAVANT SYNDROME

In their *Psychiatric Dictionary,* Hinsie and Campbell (1974) noted that in early times "idiot referred to any person who lived as a recluse in a private world" (p. 377). The French term *savant* means a person of knowledge (Hill, 1978). Rimland (1978), who coined the term *autistic savant,* described an idiot savant or autistic savant as an individual who can perform various mental feats at a level far beyond the capacity of any normal person, but whose general intellectual level is very 'low.'

Those believing that subnormal intelligence is due to mental retardation have traditionally referred to such an individual as an idiot savant. Those who believe, as Rimland does, that subnormal intellectual functioning results from autism, refer to the individual as an autistic savant. Treffert (1998, 2002), who has performed an extensive investigation, prefers the term *savant syndrome.*

Savant syndrome is very rare, with estimates of fewer than 0.5% of the developmentally disabled population presenting its symptoms. In addition, there appear to be more males with the disorder than females (6:1) (Fox, 2002).

Whether the person is labeled an idiot savant or autistic savant or as having the more inclusive savant syndrome, the presenting behavior is the same: general subnormal intelligence combined with superior intellectual abilities in one or more of the areas of music, memory, art, pseudoverbal, mathematics, geography, motor coordination, calendar, and extrasensory perception (Sacks, 1995).

SCHIZOPHRENIA, ADOLESCENT AND CHILDHOOD

Similar to adults, both adolescents and prepubertal children may suffer from Schizophrenia. Historically, both youths with either Schizophrenia or Autistic Disorder were diagnosed under the rubric of childhood psychosis. This phenomenon was likely a reflection of the fact that young people with either Schizophrenia or Autistic Disorder can have profound impairments in interpersonal functioning and substantial disturbances of thinking and behavior. Within the past three decades, it has subsequently become clear that juvenile-onset Schizophrenia and Autistic Disorder are in fact separate conditions with distinct presentations. When juveniles do suffer from Schizophrenia, they suffer from the same symptoms as adults with this condition. These may include hallucinations (most often auditory), delusions, grossly inappropriate affect, avolition, poverty of thought or speech, disorganized behavior, and disorganized speech.

However, as young people may have imaginary friends, experience eidetic imagery, and be generally less organized in their speech and behaviors than adults, accurately determining whether a child or teenager truly is suffering from a psychotic illness can be a difficult task. Further complicating accurately accepting or rejecting a diagnosis of schizophrenia in a young person is that the differential diagnosis of Schizophrenia in youths is quite extensive.

Besides developmentally expectable phenomena that are not pathological, numerous psychiatric syndromes can present with symptoms of psychosis. The most common of these include depression, bipolar disorder, Anxiety Disorders, substance-related conditions, Personality Disorders, behavioral disorders, and pervasive Developmental disorders. In addition, developmental speech and language disorders as well as the corrective self-talk that may be seen in some youths with developmental disabilities can lead an examiner to believe that a young person is experiencing hallucinations. Of note, there appears to be a group of young people who have perceptual disturbances and substantial difficulties with affect regulation, interpersonal functioning, and behavioral control that are referred to as being multidimensionally impaired. Whether these youths suffer from a condition that should be considered within the Schizophrenia spectrum of illnesses remains to be seen and is a topic of ongoing research.

It should be remembered that there are medications that are commonly prescribed to children and teenagers as well as some general medical conditions (predominantly neurological or endocrinological) that may also lead to symptoms of psychosis in young people. In fact, it appears that most children who subjectively describe hallucinations are not suffering from a psychotic illness. It is not surprising that many youths who initially receive the diagnosis of Schizophrenia are subsequently found not to be suffering from a psychotic illness.

Although the average age at onset of illness for patients with Schizophrenia is the third decade of life, approximately one third of all patients with Schizophrenia develop this illness during the teenage years. However, childhood onset of Schizophrenia is considered quite rare; very few patients develop this illness prior to age 10. As Schizophrenia occurs in approximately 1% of adults, adolescent Schizophrenia is a relatively common phenomenon. Despite this fact, a relatively modest amount of research has focused on adolescent Schizophrenia.

The longitudinal course of juvenile-onset Schizophrenia has many similarities to the natural history of this illness in adults. For example, most young people with Schizophrenia have developmental difficulties that antecede the development of the symptoms of psychosis that define this syndrome. In this age group, the onset of illness is usually not acute, but insidious. In fact, it is not uncommon for young people with Schizophrenia to have psychotic symptoms for months or years prior to being correctly diagnosed. Unfortunately, numerous studies have consistently reported that adolescent onset of Schizophrenia puts patients at high risk for a poor outcome.

Neurobiological studies have reported that young patients with Schizophrenia have findings that are distinct from typically developing youths. These include structural differences in cerebral morphology and eye tracking.

Although it is generally recommended that a multimodal approach be employed for young people with Schizophrenia, the cornerstone of treatment for adolescents and children with this illness is antipsychotic medication. Unfortunately, there have been only a few methodologically rigorous studies in this patient population. Pharmacotherapy for juvenile-onset Schizophrenia is complicated by the observation that young patients appear to be at higher risk than adults for developing antipsychotic-related extrapyramidal side effects. It also appears that earlier age at onset is associated with a greater propensity for lack of response to the typical antipsychotic agents. For these reasons, most clinicians now prescribe atypical antipsychotics to treat young people with Schizophrenia in hopes of improving the rates of symptomatic response and reducing

the rates of extrapyramidal side effects seen with the typical antipsychotics.

Open label studies have reported that risperidone, olanzapine, and quetiapine may be effective treatments for adolescents with Schizophrenia. Clozapine appears to be a rational treatment for those youths who do not respond to other forms of pharmacotherapy. However, young patients appear to be at higher risk than adults for clozapine-related neurological side effects such as seizures.

Besides pharmacotherapy, it is recommended that psychosocial interventions be employed in this condition. As young patients with Schizophrenia may have impairments in working memory and attention, many of these youths may benefit from special education services that consider these issues. It is generally recommended that psychosocial treatments not only involve the affected youth but also include the patient's family. Patients and their families may benefit from supportive and psychoeducational therapies. Youths may also derive benefit from social skills training. Families and patients often find utilizing case management and becoming part of community-based support groups to be quite helpful.

Although symptom amelioration is vital, the ultimate goal of treatment for children and teenagers with Schizophrenia is to provide these vulnerable youths the best opportunity to achieve developmentally appropriate academic goals while enjoying rich and fulfilling relationships with their peers and loved ones.

SCHOOL ADJUSTMENT

School adjustment is a multidomain construct comprising social, behavioral, and academic competencies. School interest and motivation, academic achievement, peer relationships, and classroom conduct are among the many variables involved in school adjustment. A child's school adjustment depends on the match between his or her competencies and the demands of the school environment and may fluctuate across schools, years, and classrooms or across different domains within the same year.

The school environment and the children's experiences inside and outside of school impact school adjustment. Concurrent physical and cognitive development, as well as stressful life events, peer relationship problems, and family relationships, impinge on children's school adjustment, as does the changing school environment. Within and across schools, considerable variability exists in terms of educational resources, academic and behavioral expectations, teacher and parent involvement, extracurricular activities, classroom management strategies, class size, and other aspects of the school environment. School transitions (e.g., the transition to middle school) may be particularly challenging for children due to increased social, behavioral, and academic demands. Although most children adapt to school transitions comfortably, rates of adjustment problems are elevated during school transitions.

Commonly examined markers of school adjustment include achievement and grade information, competence and problem behaviors, frequency of school absence, comfort and involvement with the school environment, anxiety or avoidance behaviors, and negative attitudes about school. Chronic poor school adjustment can lead to low achievement, school dropout, delinquency, and psychosocial maladjustment. Because adjustment in the early primary grades is related to later school adjustment, it is important to prevent poor school adjustment early in children's school careers. Interventions designed to reduce poor school adjustment target the mismatch between children's competencies and the demands of the educational environment by addressing children's competencies, parental involvement, and school environmental demands.

SCHOOL DROPOUT

The term *dropout* denotes one who officially enrolls in a program but does not complete it. As it pertains to education and schooling, a dropout is one who neither completes requirements for graduation nor receives a high school diploma. High school graduation is interpreted as receiving a high school diploma on completion of the required course credits and enrollment duration, but not an equivalence certificate. High school completion is interpreted as having fulfilled all of the requirements for high school graduation including receipt of a high school diploma, or having received an alternative form of certification, the most commonly known of which is the general equivalency diploma (GED).

Many school districts and states use the cohort method to predict future graduation numbers and define dropouts. A cohort is a group of people enrolling or participating in a specific project or program with an anticipated or expected completion date. For high school graduation, an entering 9th grade cohort or group has a four-year expected comple-

tion date. This completion is usually recognized formally by an official graduation and presentation of a high school diploma. Thus, using the cohort method to define dropouts requires different assumptions or information about students who do not graduate from secondary school within four years from the time that they enroll.

If a school computes dropout rates using the cohort method, based on students who did not graduate on time and are no longer enrolled, it may make the assumption that students who do not graduate with their cohort have left the school and are not enrolled anywhere else. The aforementioned method neglects the fact that some students could have transferred to another school, still are on schedule to graduate after four years, and should not be counted as dropouts. Other students may have been retained in their grade and are enrolled in school, so their dropout status is not determined after four years. Even if a school determines that a cohort student lacking four-year graduation status has not been retained in grade, transferred to another school, or home schooled, the student still may not be a dropout. In this case, nondropouts include students who may have graduated early by skipping a grade or who passed the GED, which technically makes them high school completers, and not dropouts.

The term *dropout,* thus, is best defined as students who entered secondary school with a particular cohort, withdrew from both formal and informal schooling, and did not complete secondary school or receive an equivalent credential. Such a conceptualization focuses more on the fact that the students withdrew from the educational system and less on the amount of time it took them to complete secondary school or the type of credential received. This definition takes into consideration factors such as grade retention, school transfer, early graduation, and alternative certification.

Additional types of definitions of dropouts include event rates and status rates. Event rate definitions of dropouts include the number of students who drop out of high school during a given academic year. Status rate definitions include the number of persons within an age range (e.g., 16–24) who have neither graduated from nor completed high school. Some reasons why students become high school dropouts include low achievement levels, the need to work, teenage pregnancy, incarceration, illness, and death.

SCHOOL LEARNING

School learning is both formal and informal. Formal learning is associated primarily with instructional processes and content applied by teaching staff. Less directly, it also stems from school-wide socialization processes, such as exposure to institutional standards and their enforcement. Informal learning at school, sometimes called the hidden curriculum, is associated with experiences of success and failure and with modeling and social persuasion.

Determinants of School Learning

A reciprocal determinist view of behavior emphasizes transactions between person and environment (Bandura, 1978; Lewin, 1951; Walsh, Craik, & Price, 1992). From this perspective, school learning is the product of the interplay among student and school variables. Each student brings to school adaptive, assimilated schemata consisting of capacities and attitudes accumulated over time, as well as current states of being and behaving. These variables transact with each other and with variables encountered at school and in coping with school requirements outside school (Adelman & Taylor, 1994).

Variables related to formal school learning encompass not only instructional processes and content but also the physical and social contexts in which instruction and related practice are the primary focus. Informal learning is the product of the many variables impinging on a student during times when instruction is not the agenda and occurs in settings such as the playing field, eating areas, and hallways, as well as in classrooms.

Types of School Learning

The impact of transacting variables can lead to four types of learning (Adelman & Taylor, 1993):

1. *Desired learning:* changes and expansion of capacities and attitudes in keeping with the school's goals
2. *Deviant learning:* changes and expansion of capacities and attitudes not in keeping with the school's goals
3. *Disrupted learning:* interference with learning functions, including possible confusion that distorts attitudes and decreases capacities
4. *Delayed and arrested learning:* little change or possibly a decay in capacities and attitudes

These outcomes are accompanied by concomitant shifts in current states of being and behaving.

Person-Environment Match

Bodies of relevant research range from basic research on learning and social learning to applied research on teaching and schooling. Theoretical underpinnings are rooted in the paradigm of person-environment match or fit (D. E. Hunt & Sullivan, 1974; J. M. Hunt, 1961; Piaget, 1952; Vygotsky, Vygotsky, & John-Steiner, 1980). With respect to for-

mal school learning, the paradigm broadly proposes that the better the match, the more likely it is that instruction will lead to desired outcomes. Conversely, the poorer the match, the less likely it is that desired outcomes will be achieved. Concern about quality of the match arises at the outset of instruction and remains throughout.

The problem of creating a good match in teaching is viewed broadly as that of establishing an appropriate challenge to the adaptive, assimilated schemata of a student. In theory, some degree of appropriate match is always feasible.

The concept of the match can be operationalized using observer or actor viewpoints or both. For example, the psychological perspective of the teacher may be the sole referent in deciding which student characteristics are considered, which instructional processes and content are used, and whether an appropriate match is established. In contrast, some teachers decide how to proceed and judge quality of fit based on student perspectives.

Matching Motivation and Developed Capability

Efforts to optimize the person-environment match focus on *both* motivation and development. Cognitive-affective theories underscore the necessity of addressing individual differences in motivation as a primary concern in creating an optimal match for learning. The focus is on four broad considerations.

First, motivation is considered a key antecedent condition—a prerequisite to school learning. Poor motivational readiness may be a cause of inadequate and problem functioning, a factor that maintains such problems, or both. Thus, strategies are called for that can result in a high level of motivational readiness (including reduction of avoidance motivation and reactance) so that a student is mobilized to participate and learn.

Second, motivation is a key ongoing process concern; processes must elicit, enhance, and maintain motivation so that the student stays mobilized. For instance, a student may value a specific outcome but may not be motivated to pursue certain processes for obtaining it or may be motivated at the beginning of an activity but not maintain that motivation.

Third, it is necessary to avoid or at least minimize conditions likely to produce avoidance and reactance. Of particular concern are activities that students perceive as unchallenging and uninteresting, overdemanding, or overwhelming and procedures that seriously limit a student's range of options or that are experienced as overcontrolling and coercive.

Finally, development of intrinsic motivation is an outcome concern (Deci & Ryan, 1985). This requires strategies to enhance stable, positive, intrinsic attitudes that mobilize a student's ongoing pursuit of desirable ends outside the school context and after graduation.

Matching a student's level of developed capability is another primary consideration in facilitating school learning. Variations in functional capacity stem from differences related to given areas of development. To facilitate an appropriate match, functional differences are accommodated through modifying processes and content to account for development lag and development that meets or surpasses expectations.

In general practice, overall patterns are considered in designing instruction to fit groups of students, with the observed patterns reflecting both accumulated capacities and attitudes. Such patterns may be described in terms of student differences, diversity, assets, deficits, and disabilities observed in a given classroom and school. Researchers and practitioners interested in patterns of functional differences find it useful for observation and measurement purposes to stress four performance dimensions: (1) rate (the pace of performance), (2) style (preferences with regard to ways of proceeding), (3) amount (the quantity of produced outcomes), and (4) quality (care, mastery, and aesthetic features demonstrated in performance; Gagne, 1985).

Environmental Factors

Facilitating school learning by focusing on the environmental side of the person-environment match has two facets: (1) directly enhancing facilitative factors and (2) minimizing extrinsic factors that are barriers to learning. Research of relevance to these matters comes from ecological and environmental psychology, systems theory and organizational research, and the study of social and community interventions. Examples of key variables include setting and context characteristics associated with school learning; characteristics of persons in the setting; and task, process, and outcome characteristics. With specific respect to barriers to learning, the focus is on factors that are insufficient to stimulate learning, exceed the student's capacity for accommodative modification, or are so intrusive or hostile that they disrupt learning.

Because teachers can affect only a relatively small segment of the physical environment and social context in which school learning occurs, increasing attention is being given to analyses of school-wide factors and combinations of school, home, and community variables.

SCHOOL REFUSAL BEHAVIOR

School refusal behavior refers to a child's refusal to attend school and to difficulties remaining in classes for an entire day. The behavior is apparent in school-age youth who miss entire school days, skip classes, or arrive to school late (excluding legitimate absences). However, the behavior also refers to youth who show severe behavior problems in the morning to try to stay home from school as well as youth who attend school with great dread. School refusal behavior affects up to 28% of youth at some time in their lives and can lead to several negative consequences. In the short term, for example, school refusal behavior may lead to family conflict, legal trouble, declining grades, social alienation, and distress. In the long term, extensive school refusal behavior may lead to delinquency, school dropout, and occupational, economic, and social problems in adulthood.

Many cases of school refusal behavior involve diverse symptoms. For example, these youth often have general and social anxiety, fear, depression, somatic complaints (e.g., headaches and stomachaches), and withdrawal. In addition, however, these youth also show many disruptive behaviors such as noncompliance, defiance, aggression, tantrums, clinging, refusal to move, and running away from school or home. In many cases of school refusal behavior, a mixture of these symptoms is present. In general, school refusal behavior is not largely related to gender, income level, or race, although dropout rates tend to be highest for Hispanics and African Americans.

Historically, school refusal behavior has been defined in different ways, and many terms have been used to describe the population. School phobia, for example, often refers to youth who are fearful of something at school, although few children in this population report specific fears. School refusal generally refers to youth who are anxious about school. This may include youth with separation anxiety or those who become worried at the prospect of being apart from parents or significant others. Truancy often refers to youth who refuse school without parental knowledge and who show other delinquent acts. The phrase *school refusal behavior* was designed as an umbrella term to include all of these children.

Treatment for youth with school refusal behavior usually begins with a systematic assessment by a school or mental health professional. In most cases, assessment includes the child, parents, school officials, and relevant others. Assessment may consist of interviews, questionnaires, observations of the family and child, standardized tests, daily ratings of distress, and reviews of school records, among other methods. A thorough medical examination should also be conducted to identify any genuine physical ailments (e.g., ulcers, migraines). Clinicians often focus on the various forms (e.g., anxiety, depression, noncompliance) as well as on the functions of school refusal behavior, or reasons why the behavior continues over time. Identified reasons for school refusal behavior include desires to escape from painful items at school, to obtain attention from parents, and to pursue tangible rewards outside of school (e.g., sleeping late, riding one's bicycle, being with friends). Many children refuse school for a combination of these reasons as well.

Common examples of school-related items that children sometimes avoid include buses, fire alarms, gymnasiums, playgrounds, hallways, animals, and transitions from one place to another (e.g., classroom to cafeteria). Common examples of school-related people that children sometimes avoid include peers (e.g., bullies), teachers, and principals. Common examples of school-related situations that children sometimes avoid include tests, recitals, athletic performances, and writing or speaking before others. Many children, however, refuse school not because of something painful there but because they wish to pursue something more appealing outside of school (e.g., time with parents or friends).

Treatment for school refusal behavior usually depends on its forms and functions. For children who refuse school because of anxiety while attending, treatment often focuses on the child to help him or her master anxiety and gradually return to school. This is done by educating the child about his or her anxiety, helping the child relax muscles and control breathing, changing irrational thoughts that might prevent attendance, and gradually reintegrating the child back into school. The latter is usually done by having the child identify classes or time periods during the day that he or she likes most (e.g., lunch and science class). The child initially attends these times only and reports different thoughts and other anxiety-based symptoms that occur. Over time, the child gradually increases classroom attendance, working to control anxiety, until full-time attendance is achieved.

For children who refuse school for attention, parent training is often used. In this approach, parents are encouraged to design set routines in the morning, daytime (if the child is home from school), and evening. A child's compliance to these routines is rewarded, and noncompliance is punished. The child is also required gradually to reattend school and face appropriate consequences for successes and failures. Parents are sometimes instructed forcibly to bring a child to school under certain circumstances (e.g., no anxiety present, cooperation with school officials, two adults present).

For children who refuse school for tangible rewards outside of school, family therapy is often used. In this approach, family members (e.g., parents and teenager) are encouraged to design contracts that increase rewards for school attendance and decrease rewards for absenteeism. The latter sometimes involves increasing supervision of the child and escorting him or her from class to class. Related procedures include communication skills training to reduce conflict and increase negotiation among family members and peer refusal skills training so that youth can appropriately refuse offers to miss school.

School refusal behavior is a serious problem that must be addressed quickly and must involve the cooperation of the child, parents, educators, and relevant others (e.g., therapist, dating partners, medical professionals). In addition, ongoing monitoring of the child is necessary to prevent relapse and address any new problems that may occur during the academic year. Early introduction to new school settings and starting the typical weekday routine one to two weeks before the start of school is often recommended as well.

SCHOOLS OF PROFESSIONAL PSYCHOLOGY

Most psychologists are educated in academic departments of psychology. Even those entering such professional fields as clinical or counseling psychology usually pursue their graduate studies in departmental programs comparable in size and administrative structure to programs in experimental, developmental, or social psychology. Increasing numbers of psychologists preparing for careers in practice, however, are educated in schools of professional psychology administratively comparable to schools of law, medicine, engineering, or business. The earliest schools of professional psychology were free-standing institutions, unaffiliated with universities. Currently, many of the schools are situated in universities, although many others continue to operate independently.

Schools of professional psychology are distinguished by several characteristics. First, their explicit mission is to prepare students for careers in practice. Second, their organizational structure is that of a school or college rather than of a departmental program. This status carries several consequences. The chief administrator is usually a dean. The academic unit is accorded a high degree of autonomy in defining its curriculum, selecting faculty, admitting students, and other matters of policy and procedure. Administrative resources and controls are relatively direct, usually through officers of the central administration in university-based schools and through boards of directors in free-standing schools. Enrollments are typically much larger than in departmental programs.

A third characteristic of professional schools is that the curriculum is specifically designed to prepare people for professional work. Supervised experience in psychological practice is therefore emphasized throughout graduate study as well as in an internship. A dissertation is required in the programs of nearly all professional schools, but the inquiry is conceived as a form of practice, not as an end in itself. Fourth, the faculties include large numbers of practitioners, and all faculty members are ordinarily expected to maintain some involvement in professional activity. Finally, the degree awarded on completion of graduate study is in nearly all cases the doctor of psychology (PsyD) degree rather than the doctor of philosophy (PhD).

The forerunner of contemporary schools of professional psychology was the program in clinical psychology at Adelphi University. When the Adelphi program was approved by the American Psychological Association Committee on Accreditation in 1957, it became the first accredited program whose primary objective was to educate clinicians for practice, instead of to educate them as scientists or scientist-practitioners. Prior to that time, all of the clinical and counseling programs in the United States and Canada had followed the Boulder model of education that was defined in a conference on the training of clinical psychologists in Boulder, Colorado, in 1949. The conference held that clinical psychologists were to be trained in academic psychology departments, prepared to conduct research as well as to practice psychology, and awarded the PhD degree on completion of graduate studies. The early Adelphi program preserved the administrative structure that was common to other departmental programs, changed the curriculum mainly by introducing more supervised clinical experience than usual, and retained the PhD as the terminal degree. It differed fundamentally from all other programs at the time, however, by affirming the legitimacy of direct education for psychological practice, with or without the promise of contributory research.

The first institution administratively organized as a school for practitioners of psychology was the Graduate School of Psychology in the Fuller Theological Seminary.

Psychologists were initially brought into the seminary faculty to train clergy in pastoral counseling, but in time they expanded their activities to form a comprehensive doctoral program combining clinical psychology with theological studies. The Fuller school was established in 1965.

Large-scale development of schools of professional psychology did not begin, however, until the California School of Professional Psychology was founded in 1969. Overwhelmed by demands for psychological services in an increasingly populous state and frustrated by repeated refusals of academic psychologists to increase the size and implicitly change the emphases of their tiny, research-oriented clinical programs, a group of practitioners resolved to create their own professional school that would be independent of any university. Faculty were to be practicing professionals, teaching on a part-time basis. The curriculum duplicated the Adelphi pattern and, as at Adelphi, the PhD degree was to be awarded to graduates. Capital funds were obtained from several private benefactors. For the first year, the founding group offered their time as administrators and faculty free of charge as an operational endowment. The plan was approved in 1969, and in 1970 the California School of Professional Psychology admitted students to its first two campuses, in San Francisco and Los Angeles. Additional campuses were opened in San Diego and Fresno over the next two years.

In 1973 another conference on professional training in psychology was held in Vail, Colorado. The conference concluded that psychology had matured sufficiently to justify creation of explicit professional programs, in addition to those for scientists and scientist-professionals. Professional schools were recognized as appropriate settings for training, and the PsyD degree was endorsed as the credential of choice on completion of graduate requirements in practitioner programs. Over the following years, schools of professional psychology were established in many locations throughout the United States. Some were in universities, and some were in free-standing institutions. Some awarded the PhD; others awarded the PsyD degree. The Graduate School of Applied and Professional Psychology, established at Rutgers University in 1974, was the first university-based professional school to offer the PsyD. At Rutgers, as in the Illinois PsyD program that preceded it, a scientist-practitioner program leading to the PhD was maintained for students interested primarily in research. This pattern—a relatively large school of professional psychology designed expressly to train practitioners and awarding the PsyD degree alongside a smaller PhD program to prepare students for research careers—has since been adopted by several other universities and independent professional schools. Toward the end of the 20th century, more than 35 professional schools were in operation, approximately half in universities and half as free-standing institutions. During this period, nearly one-third of students receiving doctorates in clinical psychology were graduated from professional schools.

As the schools have evolved, they have changed in several ways. Early faculties in free-standing schools were employed almost entirely on a part-time basis. Proportions of full-time faculty in the independent schools have increased over the years, and professional schools in universities employed large proportions of full-time faculty from the beginning. Psychological centers, analogous to the teaching hospitals of medical schools, are now an integral part of nearly all professional schools and provide the controlled settings in which faculty and students offer public services, students are trained, and research is conducted. Dissertation requirements, which were eliminated completely in some of the early schools, are now an essential part of nearly every program, though the emphasis on direct education for practice and the view of systematic investigation as a form of professional service has been retained. The PsyD degree has replaced the PhD degree in almost all of the professional schools in operation at this time.

In 1976 the National Council of Professional Schools was established to provide a forum for exchange of information among professional schools, to develop standards for the education and training of professional psychologists, and to improve in every way possible the educational process so that graduates would serve public needs most effectively. Later, the name of the organization was changed to the National Council of Schools and Programs of Professional Psychology to acknowledge the inclusion of some 20 programs that share the fundamental aims, curricula, and degree-granting practices of professional schools but differ in their smaller enrollments and departmental administrative structures. Through a series of conferences and reports, the council has conducted self-studies, defined curricula, and established means for quality assurance among its member organizations. Along with the Council of Graduate Departments of Psychology and the Councils of University Directors of Clinical, Counseling, and School Psychology, the National Council of Schools and Programs of Professional Psychology is an influential participant in shaping educational policy in American psychology.

SCIENTIFIC METHOD

The scientific method is a set of procedures designed to establish general laws through developing and evaluating theories that attempt to describe, explain, and predict phenomena. Hypotheses are made from such theories; the hypotheses are evaluated using objective, controlled, empirical investigations; and conclusions are open to public scrutiny, analysis, and replication.

Conclusions about reality can be made in at least four different ways: on faith ("I believe that God created heaven and earth"), on common sense or intuition ("I feel that women have a maternal drive"), on logic ("I think, therefore I am"), or on the analysis of empirical data (the scientific method).

The scientific approach is analytical. Complex events are analyzed into relevant variables; relationships among these variables are investigated; and theories consistent with the empirical results are created and critically evaluated. For example, if disease is more common among the poor, the scientist may postulate a set of variables that are the cause of this phenomenon, such as differences in diet, education, medical availability, environmental factors, and genetic susceptibility. Then empirical data are collected to analyze the effect of such variables on disease so that a general theory can be constructed and tested by other scientists.

The scientific method involves a critical approach to data analysis and interpretation. Issues of observer bias (the researcher who only sees or emphasizes the results that are consistent with a theory), subject bias (the subject who cooperates with the researcher by conforming to the experimenter's expectations), and confounding or extraneous variables (alternative variables that could explain the observed phenomena) receive serious attention as scientists interpret the results of their studies.

The scientific method involves a broad array of alternative procedures ranging from carefully observing the variables as they naturally occur to collecting data under controlled situations with subjects randomly assigned to conditions. Scientific research design can be grouped into three major categories. Studies can be designed to describe events, to describe correlational relationships among events, or to establish cause-and-effect relationships between events. Descriptive and correlational studies can be used to provide information for theory construction and hypothesis testing. Causal research allows the researcher to establish the direct effect of one variable on another, rather than simply to establish that two variables may correlate.

An important maxim to remember is that correlation does not imply causation. Two variables may correlate with each other, although neither causes the other. For example, literacy rates and levels of air pollution may correlate across countries. Literacy does not cause air pollution, and air pollution does not cause literacy; both variables may be caused by the demands of an industrialized society. To establish a cause-and-effect relationship, the researcher must demonstrate that by manipulating or controlling the causal variable, a change in the affected variable systematically occurs. This is a scientific experiment. Sometimes, however, this is impossible. For example, to see if being orphaned causes personality disorders, the researcher would have to select a random sample of children and make them into orphans. Because this clearly is unethical, psychologists sometimes must rely on correlational evidence and cannot provide scientific evidence for some cause-and-effect theories.

Scientists construct theories out of a collection of building blocks, and research studies and their results provide these blocks. Theories fall if the cumulative evidence does not support their construction, and theories built on a solid foundation of supporting evidence survive. A single study, by itself, rarely is considered a sufficient basis on which to accept or discard a theory. Replication (producing duplicate studies) and cross-validation (conducting studies by defining variables in different ways or using different types of samples) are necessary for the scientific community to accept the validity of a scientific theory. They also provide evidence for refining theories, to delimit more carefully conditions under which a theory holds true.

Probably one of the easiest research methodologies is the archival method, which involves seeking information from public and private records, such as newspapers or diaries. For example, research on sexism in the media could be based on content analyses of randomly selected newspapers, magazines, and radio and television programs.

Another type of scientific method involves an in-depth case study of a particular individual. Clinical psychologists may examine a patient to learn how the patient's symptoms relate to various factors in the environment or to treatment strategies. The systematic observation method can be extended from the case study of an individual to the study of entire groups. For example, naturalistic observations might be made of children as they play in a school yard or of wild animals as they roam their natural habitats. These observations can lead to theories (e.g., how dominance hierarchies are established in animals) or can be used to test hypotheses based on theories (e.g., a theory may lead to the hypothesis that children have fewer arguments when they have recently eaten).

Naturalistic observation data collected in real-life settings generally are less artificial than data collected under carefully controlled laboratory settings, so generalizing results with the former may be more valid. However, the data are only of a descriptive or correlational nature, so cause-and-effect conclusions cannot be made.

An alternative research strategy is the use of surveys, questionnaires, and structured interviews. Subjects knowingly participate as research participants and provide the data in response to specific questions. The questions can be

presented in writing (e.g., an attitude survey or personality test) or orally (e.g., an individual IQ test or public opinion poll). The quality of the data depends on the cooperation and honesty of the subjects, as well as on the quality of the questions asked. Survey techniques allow for the collection of large amounts of data under fairly standardized conditions.

Observational methods provide data for descriptive or correlational studies. Only an experiment in which the researcher manipulates the causal variable (the independent variable) and observes the effect on the affected variable (the dependent variable) can lead to conclusions about causality. It is crucial that all other variables that may affect the dependent variable (extraneous or nuisance variables) be controlled for so that results can be unambiguously interpreted.

SCL-90-R

The SCL-90-R is a 90-item self-report symptom inventory developed by Leonard R. Derogatis in the mid-1970s to measure psychological symptoms and psychological distress. It is designed to be appropriate for use with individuals from the community, as well as individuals with either medical or psychiatric conditions. The SCL-90-R assesses psychological distress in terms of nine principal symptom dimensions and three summary scores termed global scores. The principal symptom dimensions are labeled Somatization (SOM), Obsessive-Compulsive (OBS), Interpersonal Sensitivity (INT), Depression (DEP), Anxiety (ANX), Hostility (HOS), Phobic Anxiety (PHOB), Paranoid Ideation (PAR), and Psychoticism (PSY). The global measures are referred to as the Global Severity Index (GSI), the Positive Symptom Distress Index (PSDI), and the Positive Symptom Total (PST).

The SCL-90-R and its companion scales represent the current expression of a long measurement tradition. This progression proceeded most directly from a self-report instrument termed the Hopkins Symptom Checklist (HSCL) developed by Derogatis and his colleagues several years earlier than the SCL-90-R. The HSCL shares common characteristics and item content with a number of prior self-report instruments, most notably the Cornell Medical Index developed several decades before. A number of SCL-90-R items can be traced all the way back to the original self-report symptom inventory, Woodworth's Personal Data Sheet, developed to screen American Expeditionary Force soldiers for psychiatric disorder in World War I.

The SCL-90-R is one component of an integrated series of psychological distress instruments. There are two additional brief self-report scales in the series: the Brief Symptom Inventory (BSI), which is a 53-item version measuring the same nine primary symptom dimensions and three global scales, and the BSI-18, published in 2000 as a short screening version of the scale. The BSI-18 is focused on only the Somatization, Depression, and Anxiety dimensions and includes a Total summary score. Comparable dimension scores on the three instruments correlate very highly with each other. The three instruments require 12–15 minutes, 9–12 minutes, and 3–4 minutes respectively to complete.

In addition, the SCL-90 Analogue Scale and the Derogatis Psychiatric Rating Scale, two matched companion clinician rating scales, are also components in the series. The two rating scales, which differ primarily in level of complexity, enable the measurement of psychological distress status via skilled clinician judgments, measured on the same principal symptom dimensions as the respondent's self-report.

To enable more accurate and meaningful interpretation of SCL-90-R, BSI, and BSI-18 score profiles, all three instruments have gender-keyed norms. Norms were developed in such a manner that standardized scores for the various tests have actuarial properties, which means that they translate into accurate percentiles, much like college SAT or GRE scores. Norms based on community adults, community adolescents, psychiatric outpatients, and psychiatric inpatients are available for the SCL-90-R and the BSI. Adult community norms and comprehensive norms for cancer patients have been developed so far for the BSI-18.

Numerous studies testing the consistency of the tests' dimension scores across various important respondent characteristics such as gender and age have demonstrated high consistency. In addition, numerous studies evaluating the predictive and construct validity and reliability of the tests' dimension and summary scores have been conducted over the years in multiple samples and populations. These investigations have repeatedly demonstrated the instruments to be valid and consistent as measures of psychological symptoms and emotional distress. The scales have also repeatedly shown high and selective convergence with other tests that measure the same constructs and have been appropriately uncorrelated with other tests that measure distinct and unrelated constructs.

Currently, the SCL-90-R and its progeny have been utilized in close to 2,000 published clinical studies in an extraordinarily broad spectrum of applications. The instruments have been employed in diagnostic and treatment applications concerning mental health status in an extensive range of medical conditions including cardiovascular, oncologic, endocrine, neurologic, and surgical, as well as with psychiatric disorders. They have consistently demonstrated their sensitivity to pharmacotherapeutic, psychotherapeutic, and other treatment interventions and have repeatedly

proven their capacity to register systematic, clinically meaningful changes in psychological distress levels.

The SCL-90-R has been translated into 28 languages including Spanish, French, German, Italian, Russian, Portuguese, Dutch, Swiss, Japanese, Chinese, Korean, Vietnamese, Hebrew, and Arabic. The complete line of tests is published and distributed by National Computer Systems (NCS) of Minnetonka, Minnesota.

SELECTIVE ATTENTION

Within the field of cognitive psychology, selective attention refers to the differential processing of simultaneous sources of information. Perhaps the best-known real-life example of selective attention is one in which a person is capable of listening to a single voice in a room full of people talking at the same time, while apparently being oblivious to all other conversations. This instance of auditory selective attention was described by Cherry (1953) when he noted that while a person may have appeared to be selectively attending to only his or her own conversation while ignoring all other voices, that person sometimes noticed important stimuli, such as his or her own name. Cherry referred to this so-called *cocktail-party phenomenon* when he framed many of the principle questions about selective attention.

One of the main questions about selective attention concerns what factors make it easy or difficult. Much of the research on this question in auditory selective attention makes use of a dichotic listening task, in which two different auditory messages are presented simultaneously, one to each ear, via headphones. Participants are instructed to attend selectively to one of the messages and repeat, or shadow, this relevant message as quickly and accurately as possible. In general, participants have little difficulty shadowing the relevant message; that is, they can quickly and accurately repeat the relevant message in the attended ear while repeating very little, if any, of the irrelevant message in the unattended ear. Findings from modified dichotic listening task studies seem to indicate that selectivity occurs on the basis of the spatial location of the messages, as well as on the basis of frequency differences between the relevant and irrelevant messages. For example, if each of the two messages is played simultaneously at equal intensity in both ears (eliminating differences in spatial location as determined by variances in interaural intensity) using the same voice (eliminating differences in frequency), selectivity of just one message becomes considerably more difficult (Cherry, 1953). Selectivity improves, however, if the voices of the two messages differ in pitch; for example, the ease of shadowing increases when the irrelevant message is delivered by a different gender (Treisman, 1964). Shadowing is also improved when spatial localization is produced by introducing even moderate differences in interaural intensity between the two messages (Treisman, 1964).

The factors affecting the ease of selective attention has been an issue also with respect to the visual modality. That is, what factors make it easier or more difficult for a person to attend selectively to a particular visual stimulus while excluding others? Visual selective attention is often studied using a visual filtering task in which participants are asked to attend selectively to one visual stimulus embedded within an array of visual distracter items. Other tasks involve superimposing two different videotaped events onto a single video. Participants are instructed to selectively attend to one visual scene and press a button whenever an unusual event occurs in the relevant scene. Results seem to suggest that the ease with which participants can selectively attend to the relevant visual stimulus depends on the degree to which the relevant and irrelevant stimuli differ in terms of simple physical attributes, such as location, color, size, and brightness (Pashler, 1998).

Since Cherry first drew attention to the topic of selective attention in the early 1950s, two structural models of selective attention have been proposed. So-called early selection models of Broadbent (1958) and Treisman (1964) viewed selective attention in the context of an information-processing model in which incoming stimuli are successively transformed from basic sensory attributes into more complex semantic representations. Selective attention was seen as a type of filter or bottleneck that restricted the flow of information through the system. According to Broadbent and Treisman, this bottleneck occurred early in the information-processing system, such that only low-level perceptual characteristics could be perceived prior to attentional selection. Thus, early-selection theories suggest that higher level semantic characteristics cannot be perceived early in processing. In contrast, late-selection theories hold that the bottleneck occurs later in the information-processing system, such that higher level, abstract processing of meaning can occur before attentional selection takes place (Deutsch & Deutsch, 1963). Even though several decades have passed since the articulation of this issue, the question of whether selection occurs early or late has remained largely unresolved.

This question of whether selective attention takes place early in stimulus processing, before semantic analysis of any stimulus, or whether it takes place later in processing, after semantic analysis of all stimuli, has preoccupied researchers for many years. Research on this question also makes use of the dichotic listening task. Results from these types of studies show that participants can remember almost nothing about the content of the irrelevant message but are able to note if the gender of the speaker is switched or if the irrelevant message is replaced with a tone (Cherry,

1953). These results seem to indicate that selection takes place before the stimulus has been analyzed on the basis of its meaning. However, other studies have shown that participants are able to notice the insertion of their name into the irrelevant message (Moray, 1959) and that they sometimes shift their shadowing from the relevant message to the irrelevant message when, midway through a shadowing task, messages are switched between ears (Treisman, 1960).

In visual modality studies, evidence for semantic processing of unattended stimuli is also somewhat mixed. Experiments reported by Underwood (1981) involved presentation of central (relevant) and right (irrelevant) parafoveal word stimuli in order to determine whether semantic attributes of the irrelevant word would influence processing of the relevant word. Following presentation of the word stimuli, participants were asked to respond by naming the category to which the relevant word belonged. It was found that the latency of the category-naming response was influenced by the semantic relationship between the relevant and irrelevant words. However, in several other studies of a similar nature, no semantic biasing or priming effects were observed (Inhoff & Rayner, 1980; Paap & Newsome, 1981).

SELF-CONTROL

Psychology has had a long and stormy relationship with concepts relating to human agency. Willpower, will, and self-control have all been part of the battle. Late nineteenth century psychology textbooks still discussed will and self-control in terms of the individual as an initiator of action. American psychology after G. Stanley Hall, and German psychology after Ach and Lewin, moved away from those notions toward concepts of drive and motive and voluntary and involuntary physiological responses. This trend represented an effort in psychology to disavow its parent, philosophy, and avoid potential mentalistic and teleological concepts of human action.

But the concept of self-control will not go away. It is an essential component of philosophy related to classic terms such as choice, free will, determinism, and self. Self-control is relevant in law and society in the sense of personal responsibility for one's actions, competence to stand trial, and punishment and consequences for behavior. It plays a role in religious and spiritual traditions where concepts of self-restraint, internal self-regulation, and management of external behavior (e.g., right speech, right action) are integral.

Views of Self-Control in Different Psychological Traditions

Each psychological tradition has been forced to grapple with and define self-control. For the classical Freudian, it was "where id was, ego shall be"; for the ego psychologist, it was for the autonomous ego to learn to regulate and exercise greater independent control and mastery over instincts.

Early radical behaviorists argued that the concept of self-control was unnecessary because all behavior could be determined by environmental causes. More recent views place a prime importance on the capacity of the individual to develop greater cognitive and behavioral self-control and self-regulation. Self-control has been defined by various behavioral theorists as the response of an organism made to control the probability of another response, engaging in a low probability behavior in the absence of immediate external constraints, delay of gratification, and self-efficacy.

Humanistic psychologists have stressed the importance of the individual moving away from other direction toward self-direction and autonomy. Existentialists argue that personal control is realized through exercising our freedom to make choices. Transpersonal psychology holds two seemingly paradoxical views regarding control: (1) Individual efforts are important to gain active control of our self, mind, and passions, and (2) surrendering active control is also essential, and this, too requires a type of self-control—the control to let go, forgive, and accept.

Toward Multideterministic Models of Self-control

The majority of current thinking in psychology has moved beyond simplistic unideterministic, absolute models of personal control that argue that there is only one major variable involved in human agency. Examples of unideterministic models include radical behaviorists (like strict cultural determinists) who posited that there was no such thing as personal self-control. Radical existentialists maintained that the individual was totally responsible for personal self-control. Biological determinists theorized that biology at the cellular, biochemical level determines thought and behavior (control upward).

Current, larger models involve reciprocal (and omni-) determinism suggesting that control involves a mutual interaction among many variables. For example, the environment influences the individual, but the individual can exert personal control on the environment (self-controlling the environment). Further, just as biology can influence consciousness, consciousness can influence biology (self [as consciousness] controlling the mind and behavior).

These larger models have also refined thinking about the *self* in *self-control.* Self-control can be seen as potentially occurring on multiple levels. When a person controls him- or herself, what is occurring descriptively is that the self as agent is having an effect on the self as object. From this descriptive viewpoint (not implying self-duality), the self as agent or object can be referred to linguistically as the whole person (totality); one's mind, brain, cognitions, and feelings; one's body; or one's behavior. For example, I (self as agent: totality) am learning to control my anger (self as object: feelings). My mind (self as agent) is helping me learn to relax my body (self as object: body). By practicing meditation (self as agent: cognitive focusing), I am learning to be more forgiving and accepting (self as object: emotions).

Thus, self-control as a multidimensional construct implies a process movement away from reflexive action to conscious choice awareness and personal responsibility. The belief system on which the construct is based is that individuals are not absolutely determined, can gain more autonomy and free choice, and have the ability to effect change in their lives on some level.

Self-Control Strategies and Goals of Self-Control

A self-control strategy refers to a family of techniques that an individual practices in a regular, systematic manner to influence cognitive and behavioral activity in a desired direction. Self-control techniques include behavioral self-control, hypnosis, biofeedback, meditation, and guided imagery, among others. These techniques utilize certain components, which can be analyzed and compared based on the following variables: nature of cognitive statements and instructions, type of images used, where and how attention is focused, what is self-observed, the nature of breath regulation, environmental strategies (e.g., stimulus cues), and behavioral practices.

During the past three decades psychologists and health care professionals have developed and refined a number of effective control strategies to help individuals change self-cognitions, reinterpret and transform emotions, change perceptions, and modify their behaviors. These strategies involve one of three goals: to help the individual change the environment, to change their behavior, and to change their consciousness (e.g., cognitive control to impose meaning on or interpret events).

Critical in the development of self-control and the use of self-control strategies is the concept of choice, or decisional control: that is, What is the goal for which the person wishes to develop and exercise self-control? Several schools of thought are now beginning to integrate the traditional change model of self-control with an acceptance model of self-control. For example, a person who dislikes his or her body image may make a choice to learn self-control strategies involving an assertive change mode of control such as exercising more and developing healthier eating habits. Or such individuals may choose to learn self-control strategies involving meditation and cognitive instructions of self-acceptance to honor their bodies as they are. Depending on the person and the circumstances, either self-control goal may be healthy and bring about a sense of control and well-being.

Further, the two goals do not need to be an either-or, mutually exclusive situation: An individual can learn to accept and honor his or her body as it is while at the same time developing an exercise program and healthier eating habits. Although there is no comparable concept in Western psychology (or even in English), the Chinese language suggests this possibility of harmonizing change and acceptance modes of self-control through *dongjing:* the proper and balanced combination of the two different modes of control.

By noticing how frequently thoughts, feelings, and actions intersect with issues of self-control, we can begin to realize that this construct, though multifaceted and difficult to grasp, is a critical aspect of our daily lives: personally, interpersonally, and societally.

SELF-DETERMINATION

The science of psychology was built on the assumption that behavior is lawful. This led behaviorists to propose that behavior is controlled by associative bonds that develop through reinforcement processes (Hull, 1943; Skinner, 1953). From that perspective, behavior is beyond people's control; in other words, it is not self-determined.

Beginning in the 1950s, cognitive concepts such as expectancies, goals, and decisions replaced associative bonds as the process underlying behavioral regulation (Lewin, 1951; Tolman, 1959). People were said to behave in order to attain goals, outcomes, or reinforcements. Thus, their behavior is not controlled by past reinforcements but depends on decisions to pursue future outcomes. As Nobel laureate Roger Sperry (1977) stated, people do have some capacity to choose their own behaviors based on their thoughts and feelings.

This change in focus from past reinforcements to expectations about future outcomes was a dramatic shift, and social learning theorists such as Bandura (1989) argued that self-motivation involves people pursuing outcomes that they feel able to attain. Implicit in that view is the assumption that there is only one type of motivation, that motivation varies only in amount. The amount of people's motivation depends on their expectations that behavior will lead to reinforcements and on their feeling competent to do the behavior.

Other theorists have identified serious problems with that perspective (Deci & Ryan, 1991). Even casual reflection reveals that there are different kinds of motivation. In other words, motivation varies not only in amount but also in orientation or type. Sometimes people behave with a full sense of willingness, with a sense of freedom and excitement, finding the task quite enjoyable. Other times they behave while feeling coerced, with the sense that they have to do the behavior even though they do not want to. In both cases they are motivated, and they might even have equal amounts of motivation; however, the type or orientation of motivation is clearly very different, and the consequences of the two types of motivation will be different.

As an example, think of employees who are highly motivated to produce a product because they are paid a certain amount for each unit produced. They would probably feel pressured to produce, and they might even feel a sense of alienation from the job itself. After all, the job is just an instrument for obtaining money. In contrast, think of employees who are motivated because they have the desire to perform well and because they find the job interesting and important. They too might have a very high level of motivation, but unlike the others they would be working with a sense of commitment and enjoyment. The job itself is important to them.

These two examples convey the distinction between *intrinsic motivation,* which refers to doing something because it is inherently interesting or enjoyable, and *extrinsic motivation,* which refers to doing something because it leads to a separate outcome. Intrinsically motivated behaviors do not require reinforcements and thus do not operate by the same expectancy principles as extrinsic motivation. In fact, intrinsic motivation is the prototype of self-determination, whereas extrinsic motivation that involves feeling coerced by reward contingencies does not constitute self-determination. In short, in spite of the social-learning perspective, only some motivated behaviors are self-determined, volitional, and agentic.

Self-determination involves experiencing a sense of choice about what one is doing, and research has now shown that while intrinsic motivation is the model of self-determination, extrinsically motivated behavior can also become self-determined. This occurs through the processes of internalization and integration of behavioral regulations (Ryan & Deci, 2000). Internalization involves taking in a regulation, and integration involves fully transforming it into one's own. Thus, there are different forms of extrinsic motivation: one in which the regulation is external to the person; one in which the regulation has been internalized but not integrated; and one in which the regulation has been fully integrated. Although the latter two both represent internal motivation, only integration involves a full sense of volition and personal commitment.

Together, intrinsic motivation and fully integrated extrinsic motivation are the bases for self-determination, and more than three decades of research have shown that the quality of experience and performance varies as a function of the degree to which a behavior is self-determined. Those behaviors that are more self-determined are associated with a stronger sense of personal commitment, greater persistence, more positive feelings and self-perceptions, better quality performance, and better mental health (Deci & Ryan, 1985). Thus, given the relation of self-determination to both personal experience and performance outcomes, the critical question concerns how to promote self-determination.

Studies have shown that one factor affecting how self-determined people will be in doing behaviors is whether the behaviors are valued by others to whom they feel connected. This suggests that the starting point for facilitating self-determination in others is providing them with a sense of personal relatedness. Further, people must feel competent at the target behaviors in order to be self-determined in carrying them out. For example, people will be more likely to internalize and integrate a goal if they have the relevant skills and understanding to succeed at it. Thus, supporting competence by offering optimal challenges and providing effectance-relevant feedback will also facilitate self-determination. Finally, for people to become self-determined with respect to a behavior, they must grasp its meaning to them, have their own perspective acknowledged, and feel a sense of choice about doing the behaviors. In other words,

facilitating self-determination in others also requires providing them with supports for autonomy (Deci, Eghrari, Patrick, & Leone, 1994; Deci & Ryan, 1991).

In sum, self-determination, which is based in intrinsic motivation and integrated extrinsic motivation, has been associated with a variety of positive performance and affective outcomes in the areas of education, parenting, work, health care, and sport and has been found to depend on interpersonal supports for relatedness, competence, and autonomy (Ryan & Deci, 2000).

SELF-EFFICACY

People contribute to their own functioning and well-being through mechanisms of personal agency. Among the mechanisms of personal agency, none is more central or pervasive than people's beliefs in their capability to exercise control over their own functioning and over environmental events (Bandura, 1997). Efficacy beliefs are the foundation of human agency. Unless people believe that they can produce desired results by their actions, they have little incentive to act or to persevere in the face of difficulties. That self-efficacy beliefs play an influential role in human adaptation and change is amply documented by meta-analyses that combine the findings of numerous studies in different spheres of functioning (Holden, 1991; Holden, Moncher, Schinke, & Barker, 1990; Multon, Brown, & Lent, 1991; Stajkovic & Luthans, 1998).

Sources of Self-Efficacy

People's beliefs about their efficacy are constructed from four principal sources of information. The most effective way of instilling a strong sense of efficacy is through mastery experiences. Successes build a robust belief in one's personal efficacy. Failures undermine it, especially if frequent failures occur in early phases in the development of competencies. Development of resilient self-efficacy requires experiences in overcoming obstacles through perseverant effort. The second method is by social modeling. Models serve as sources of competencies and motivation. Seeing people similar to oneself succeed by perseverant effort raises observers' beliefs in their own capabilities. Social persuasion is the third mode of influence. Realistic boosts in efficacy can lead people to exert greater effort, which increases their chances of success. People also rely partly on their physiological and mood states in judging their capabilities. The fourth way of altering self-efficacy beliefs is to enhance physical states, reduce stress and depression, and correct misinterpretations of somatic states.

Efficacy-Activated Processes

Self-efficacy beliefs regulate human functioning through four major processes. They include cognitive, motivational, emotional, and selection processes.

Cognitive Processes

The effects of self-efficacy beliefs on cognitive processes take various forms. Much human behavior, being purposive, is regulated by forethought embodying cognized goals. Personal goal-setting is influenced by self-appraisal of capabilities. The stronger the perceived self-efficacy, the higher the goal challenges people set themselves, and the firmer their commitment to meeting them.

Most courses of behavior are initially shaped in thought. People's beliefs about their efficacy influence the types of anticipatory scenarios they construct and rehearse. Those who have a high sense of efficacy visualize success scenarios that provide positive guides for performance. Those who judge themselves as inefficacious are more inclined to visualize failure scenarios, which undermine performance by dwelling on personal deficiencies and on how things will go wrong. A major function of thought is to enable people to predict the occurrence of events and to create the means for

exercising control over those that affect their daily lives. It requires a high sense of efficacy to stick with the laborious cognitive activity needed to extract predictive and operational knowledge from information that contains many ambiguities, redundancies, and uncertainties. The stronger the perceived self-efficacy, the more effective people are in their analytic thinking and in constructing successful courses of action.

Motivational Processes

Beliefs of personal efficacy play a central role in the self-regulation of motivation. Most human motivation is cognitively generated. In cognitive motivation, people motivate themselves and guide their actions anticipatorily through the exercise of forethought. They form beliefs about what they can do; they anticipate likely outcomes of prospective actions; and they set goals for themselves and plan courses of action designed to realize valued futures. Different theories—attribution theory, expectancy-value theory, and goal theory—have been built around these various forms of cognitive motivators.

Perceived self-efficacy operates as a central factor in each of these forms of cognitive motivation (Bandura, 1986, 1991). Efficacy beliefs bias the extent to which people attribute their successes and failures to personal capabilities or to external factors. People act on their beliefs about what they can do, as well as their beliefs about the likely outcomes of various actions. The effects of outcome expectancies on performance motivation are, therefore, partly governed by self-beliefs of efficacy. There are many activities which, if done well, guarantee valued outcomes, but they are not pursued by people who doubt they can do what it takes to succeed. Perceived self-efficacy also contributes in several ways to motivation through goal systems (Bandura, 1991; Locke & Latham, 1990). It is partly on the basis of efficacy beliefs that people choose what challenges to undertake, how much effort to expend in the endeavor, and how long to persevere in the face of obstacles and failures.

Human attainments and positive well-being require an optimistic sense of personal efficacy (Bandura, 1986, 1997) because ordinary social realities are strewn with difficulties. In a world full of impediments, failures, adversities, setbacks, frustrations, and inequities, people must have a robust sense of personal efficacy to sustain the perseverant effort needed to succeed.

Affective Processes

People's beliefs in their coping capabilities also play a pivotal role in the self-regulation of affective states (Bandura, 1997). There are four principal ways in which self-efficacy beliefs affect the nature and intensity of emotional experiences. Such beliefs create attentional biases and influence how potentially aversive life events are construed and cognitively represented; they affect the exercise of control over perturbing thought patterns, and they sponsor courses of action that transform distressing and threatening environments into more benign ones (Williams, 1992). These alternative paths of affective influence are amply documented in the self-regulation of anxiety arousal and depressive mood.

People who believe they can exercise control over potential threats do not conjure up apprehensive cognitions and, hence, are not distressed by them. But those who believe they cannot manage potential threats experience high levels of anxiety arousal. They dwell on their coping deficiencies, view many aspects of their environment as fraught with danger, magnify the severity of possible threats, and worry about perils that rarely, if ever, happen. Through such inefficacious thought they distress themselves and constrain and impair their levels of functioning. It is not the sheer frequency of perturbing cognitions, but the perceived inefficacy to turn them off, that is the major source of distress.

In addition, people with a high sense of efficacy to manage unpleasant emotional states by palliative means can get themselves to relax, direct their attention to favorable things, calm themselves, and seek support from friends, family, and others. For those who believe they can get relief in these ways, anxiety and sadness are easier to tolerate.

A low sense of efficacy to gain and maintain what one values contributes highly to depression in at least three ways. One route is through unfulfilled aspiration. People who impose on themselves standards of self-worth which they judge unattainable drive themselves to bouts of depression. A second efficacy route to depression is through a low sense of social efficacy to develop social relationships that bring satisfaction to one's life and cushion the adverse effects of chronic stressors. A low sense of social efficacy contributes to depression both directly and by curtailing development of socially supportive relationships. The third route to depression is through thought-control efficacy. People live in a psychic environment largely of their own making. Much human depression is cognitively generated by dejecting, ruminative thought. A low sense of efficacy to exercise control over ruminative thought contributes to the occurrence, duration, and recurrence of depressive episodes.

Selection Processes

The final way in which self-beliefs of efficacy contribute to human adaptation and change concerns selection processes (Bandura, 1995). Beliefs of personal efficacy shape the courses of lives by influencing selection of activities and environments. People tend to avoid activities and situations they believe exceed their coping capabilities, but they readily undertake challenging activities and pick social environments they judge themselves capable of handling. Any factor that influences choice behavior can profoundly affect the direction of personal development. This is because the social influences operating in selected environments con-

tinue to promote certain competencies, values, and interests long after the decisional determinant has rendered its inaugurating effect. Career choice and development is but one example of the power of self-efficacy beliefs to affect the course of life paths through choice-related processes (Lent, Brown, & Hackett, 1994).

People with a low sense of efficacy in a given domain of functioning shy away from difficult tasks, which they tend to perceive as personal threats; have low aspirations and weak commitment to the goals they choose; turn inward on their self-doubts instead of thinking about how to perform successfully; dwell on obstacles, the consequences of failure, and their personal deficiencies when faced with difficulties; attribute failures to deficient capability; slacken their efforts or give up quickly in the face of difficulties; are slow to recover their sense of efficacy after failures or setbacks; and are prone to stress and depression. People who have a strong sense of efficacy, by contrast, approach difficult tasks as challenges to be mastered rather than as threats to be avoided; set challenging goals and sustain strong commitment to their goals; concentrate on how to perform successfully rather than on disruptive personal concerns in the face of problems; attribute failures to insufficient effort or deficient knowledge and skills that are remediable; redouble their effort in the face of obstacles; quickly recover their sense of efficacy after failures or setbacks; and display low vulnerability to stress and depression.

SELF-FULFILLING PROPHECY

Historically, prophecies have been generally associated with individual prophets as in the Old Testament or individual deities as in the case of the Greeks. Prophets and prophecies in the traditional meaning are not in vogue now, but it is now being recognized that social beliefs and expectations often affect social reality. The phenomenon of social beliefs affecting social facts or creating a social reality is referred to as self-fulfilling prophecy. A popular example of such a phenomenon from the 1930s would be a run on a bank and a resulting foreclosure of that bank because of rumors of financial risks associated with that bank, despite its financial solvency.

The term self-fulfilling prophecy is associated with two sociologists, W. I. Thomas and Robert K. Merton. Merton popularized the concept of self-fulfilling prophecy, which was based on the idea posited by Thomas, now often referred to as the Thomas theorem. The basic premise of the Thomas theorem is that "if men define these situations as real, they are real in their consequences" (Janowitz, 1966, p. 301). The idea, however, was not new, and many famous names in the past, including Shakespeare, Pirandello, and Freud, had made use of it. Moll, a hypnotist, distinctly stated that prophecy causes its own fulfillment in the case of his subjects. The concept addresses the general relationship between social beliefs and expectations and their outcomes. According to Merton, the self-fulfilling prophecy is, in the beginning, a false definition of the situation evoking a new behavior, which makes the originally false conception come true (Merton, 1968, p. 477). A self-fulfilling prophecy can take place at an individual, group, or organizational level and could be international in scope. An individual may have self-imposed expectations or expectations from external sources. The concept of self-fulfilling prophecy can also be used to illustrate prejudices toward minority groups around the world.

Application and Testing

The concept has been refined, modified, extended, tested, and incorporated in many disciplines such as sociology, psy-

chology, education, child development, military, business, industry, and health practices. A number of other terms are being used as synonyms, variations, and antonyms for self-fulfilling prophecy. In addition to the term self-defeating prophecies, suggested by Merton, variations of the theme called self-destroying prophecies, self-frustrating predictions, and self-confirming predictions have appeared in the literature (Sztompka, 1986, p. 234). Similarly, in educational research, the term Pygmalion effect is used instead; Galatea effect is used to indicate rising expectations of the employees, and Golem effect is used to denote negative consequences in industrial research.

Labeling theory in sociology asserts that when deviant behavior earns an individual a label as a deviant, the reaction of others toward him because of that labeling may push the individual to accept the identity of a deviant and thus further commit other deviant acts. Some psychologists who have studied this process for the last 50 years are of the opinion that beliefs and expectations can create individual or social realities (Fleming & Manning, 1994). Allport (1950), for example, suggested that suspicion of hostile intentions between two countries could trigger a conflict between them. In experimental situations, the self-fulfilling prophecy is called expectancy effect and demand characteristics. These characteristics were also experimentally demonstrated by Rosenthal (1966). Psychologists have extended their research in self-fulfilling prophecy to nonverbal behavior and less formal types of interaction and effects of labeling inside and outside organizations such as mental institutions. Psychologists in general have tried to provide the dynamics of the process, sequence, and combination of motives, the attitudes and goals involved in self-fulfilling prophecy, and the constraints and conditions under which it works. In the medical literature, the self-fulfilling prophecy or placebo effect to relieve pain or affect healing has been very widely documented since the 1940s, from the treatment of warts to the healing of damaged tissues. The prevalence of voodoo is another example of the power of placebo effect.

Educational research studies have indicated that the teacher's positive or negative expectations often come to be shared by the students, frequently in the direction of the prior anticipations of the teachers, and this phenomenon is called the Pygmalion effect after the Greek mythological character (Jones, 1977; Rosenthal, 1966; Tauber, 1997). Although there is criticism of this concept in the field of education that it is self-fulfillment of the self-fulfilling prophecy (Wineburg, 1987), teacher expectation bias effects have been acknowledged by many educational researchers. Similarly, parental expectations of children are often shared by the children themselves. In the military, business, and industrial research, the concept of self-fulfilling prophecy has been used to increase productivity, sales, and performance. Workshops are conducted in order to outperform the competition by communicating to the employees that they are capable of meeting the increased expectations (Eden, 1990).

What happens when prophecy fails? A book by the same title gives an interesting account of the rationalizations involved in a direct prophecy about the end of the world, which did not materialize (Festinger, Riecken, & Schachter, 1956). Philosophers and psychologists use the concept of confirmatory bias to account for the acceptance of a statement that was only partially confirmed and partially proved to be false. Of course, many prophecies are neither self-fulfilling nor inevitable. All prophecies are subject to change, failure, or defeat. Merton has pointed out that the initial definition of the situation needs to be abandoned before the prophecy can be broken. The dire predictions about Y2K were self-defeating because a massive number of projects were established to attack the problem.

The research literature attests to the scope of the applications as well as to the limitations of the phenomenon of self-fulfilling prophecy. For example, labeling is not very effective in the case of major offences such as murder. In the case of Y2K, for example, some people decided not to travel on the eve of the year 2000, but some others ignored it. Such prophecies will continue to provide interesting case studies, as they illustrate the possibilities and problems involved in understanding the process, power, and limitations of the phenomenon of self-fulfilling prophecy.

SELF-HELP GROUPS

The primary goal of self-help groups (sometimes called mutual aid or mutual help groups) is to achieve psychological or behavioral gains for their members, who typically address a single problem or condition and who are committed to two principles: that people who are coping or have coped with a personal problem are better helpers than professionals who do not have firsthand experience and that such people help themselves by helping each other.

Origins and Present Status

Various strains of ancestry have been cited: a tradition of mutual support by family, community, church, and ethnic group members; trade unions and cooperatives; Christian group-confessional religious practices; and the American (U.S.) value of self-reliance. Whatever the antecedents, contemporary self-help groups have evolved at least partly to meet therapeutic needs that often are not, or are not adequately, dealt with by existing social institutions.

Alcoholics Anonymous (AA) is the oldest, largest, and best known ongoing self-help group. Founded in 1935 by Bill W. and Dr. Bob, it is organized by and for alcoholics (with offshoots Al-Anon and Al-Ateen for relatives and friends). Although described in the 1937 publication *Alcoholics Anonymous,* AA was little known to the general public until a 1944 *Saturday Evening Post* article. It now has well over a million members in 100 countries. Its 12-step program has been adopted by many other groups (e.g., Gamblers Anonymous, Overeaters Anonymous, Narcotics Anonymous, Debtors Anonymous). Other early self-help organizations are Recovery, Inc., founded in 1937 by psychiatrist Abraham Low for former patients of mental health institutions, and Synanon, founded in the 1950s by Charles Dederich for drug addicts (and, later, ex-convicts).

Self-help groups grew in number in the late 1950s and early 1960s. One directory listed 265 in 1963. Another listed 650 local chapters from 120 different self-help organizations in 1982 in the Chicago area alone. In 1993 Alfred H. Katz estimated 750,000 self-help groups in the USA with 10 to 15 million members. Some see this growth as a major movement in psychotherapy, a fourth force following the third force of humanistic psychotherapy.

In 1976 both the *Journal of Applied Behavior Science* and *Social Policy* had special issues on self-help. U.S. Surgeon General C. Everett Koop organized a national workshop on self-help and public health in 1987. There are national and state self-help clearinghouses of information and similar centers in Canada, Australia, Israel, Japan, and a dozen European countries.

Types of Groups

Levy's (1976) classification of self-help groups is instructive:

- *Type I.* This aims primarily at behavioral control or change, especially for addicts and compulsives. Examples are AA, Gamblers Anonymous, TOPS (Take Off Pounds Sensibly), and Parents Anonymous (coping with child-abuse tendencies).
- *Type II.* Members of this type share a stressful status or condition, sometimes a particular physical health problem (e.g., Mended Hearts for those who have had heart surgery; Make Today Count for cancer patients, families, and friends; Reach to Recovery for women who have had mastectomies; in 1995 Riessman and Carroll claimed a self-help group for every major illness listed by the World Health Organization); others have members coping with mental illness (e.g., Schizophrenics Anonymous); still others focus on such crises as rape, murder of one's child, and suicide; and another subcategory deals with life transitions (Geriatric Rap, Widow-to-Widow, Parents Without Partners) or transitions toward normality (for former mental patients, ex-convicts, Vietnam War veterans).
- *Type III.* These groups include people felt to be discriminated against because of sex, race, class, or sexual orientation.
- *Type IV.* Individuals in this type work toward general self-actualization and enhanced effectiveness. Levy (1976) includes Mowrer's (1972) Integrity Groups under this classification, which covers many consciousness-raising groups.

Therapeutic Factors in Self-help Groups

1. *Shared experiences or situations,* helping people feel immediately understood and thus not psychologically alone. Commonality tends also to reduce defensiveness and encourage self-revelation with its cathartic utility and reduction of shame.

2. *Helping others.* The helper therapy principle of self-help groups, first enunciated by Frank Riessman in 1965, posits that the more group members help others, the more they are helped themselves. Helpers feel greater competence, make learning gains, receive social approval, practice and thereby self-reinforce desirable role behavior, and achieve more objectivity concerning their particular problem.
3. *Ongoing support network.* Members receive supportive praise at their meetings. Typically, support extends virtually around the clock with members on call.
4. *Information sharing.* Much benefit comes from receiving information, whether technical or part of folk wisdom, including everything from explaining medical jargon to child-rearing advice. Some groups keep abreast of current research and treatment modalities.
5. *Finding models.* Membership provides opportunities to observe how others cope effectively.
6. *Gaining feedback.* In the openness and honesty that typify self-help groups, members' behaviors tend to be accurately observed and commented on. Such directness, in a supportive atmosphere, helps people find their way.
7. *Learning special methods.* With some self-help groups such as AA and other 12-step programs, successful coping is closely linked to following special procedures. Members learn and perpetuate them, and many find the structure valuable.

Self-help Versus Professional Psychotherapy

The relationship between self-help groups and professional and institutional helpers has varied from antagonism to close cooperation. Professional group psychotherapy typically differs from self-help in significant ways: Professionals have formal training and credentialing; their help is paid for and time-limited; they do not expect reciprocal emotional support; and they operate from an explicit theoretical base that claims empirical support. For some self-help groups, independence from the authority, methods, and funding of professionals is a matter of principle (and sometimes of antiprofessional rhetoric).

But even self-help advocates acknowledge ways in which professionals have started, advised, and legitimized some groups. Among professional therapists who have founded self-help groups are Low (Recovery, Inc.), Mowrer (Integrity Groups), and Phyllis Silverman (Widow-to-Widow). Perhaps a third of self-help groups began with assistance of professional helpers. Interaction among professionals and laypersons often occurs in groups related to physical health. Organizations such as AA gain endorsements by psychiatrists and clinical psychologists. The National Institute of Mental Health has sponsored studies of self-help groups and of their interactions with professional workers and institutions. Cooperation between self-help groups and professional psychologists and psychotherapists seems to be increasing.

Evidence of the effectiveness of self-help groups is largely anecdotal. Research is difficult by their very nature (i.e., anonymity, transient membership, lack of record keeping). Aside from such issues, challenges to some groups might be raised about questionable founding premises and pressures toward conformity. But Riessman and Carroll (1995) put the movement in a larger psycho-socio-political context: "A major reason for the current resonance of the self-help approach relates to the significant world problems to which a self-help model is potentially responsive, including widespread feelings of powerlessness and alienation . . . and of isolation; widespread addictions; . . . the tremendous expansion of chronic illnesses," and a host of other social, political, and even professional problems and limitations.

SELF: LOOKING-GLASS CONCEPT

The looking-glass concept of self is commonly attributed to Charles Horton Cooley (1902), who, in elaborating on William James' (1890) discussion of the social self, suggested that a reflected self arises when individuals appropriate a self-feeling on the basis of how they think they appear in the eyes of other individuals. Cooley stated, "A social self of this sort might be called the reflected or looking-glass self: *Each to each a looking-glass/Reflects the other that doth pass*" (1902, p. 184).

While Cooley is credited with the looking-glass metaphor, its appearance in literature can actually be traced to the works of Adam Smith, who, in *The Theory of Moral Sentiments,* stated, "We examine our persons limb by limb, and by placing ourselves before a looking-glass, or by some expedient, endeavor as much as possible to view ourselves at the distance and with the eyes of other people" (1892, p. 162). Society, he suggested, provides the mirror in which individuals can see themselves as spectators of their own behavior: "This is the only looking-glass by which we can, in some measure, with the eyes of other people, scrutinize the propriety of our own conduct" (1892, p. 164).

The metaphor of the looking glass carries a double meaning in Smith's and Cooley's formulations. In everyday life, individuals see their faces, figures, and dress in the glass and "are interested in them because they are ours, and pleased or otherwise with them according as they do or do not answer to what we should like them to be" (Cooley, 1902, p. 184). In interactions with others, it is necessary for one to imagine how he or she appears in the eyes of the other. The other becomes the mirror and forms his or her interpretation of the individual given that individual's gestures, facial expressions, and statements. Anselm Strauss has captured this relationship with the other in the title of his essay on identity, "Mirrors and Masks" (1958).

The self-idea that incorporates self-feeling, according to Smith and Cooley, has two principal components—the imagination of the other's judgment of that appearance and some sort of "self-feeling, such as pride or mortification" (Cooley, 1902, p. 184). The self-feeling is appropriate on the basis of the imagined judgment of the other. This imputed sentiment, taken from the other and directed inward, to the self, moves the individual. The evaluation of the other, in whose mind the person sees the self, determines this self-feeling. Cooley states, "We are ashamed to seem evasive in the presence of a straightforward man, cowardly in the presence of a brave one, gross in the eyes of a refined one, and so on" (1902, p. 184).

The basic structure of self-feeling is threefold, involving (1) a feeling for one's self, (2) a feeling of this feeling, and (3) a revealing of the self through this feeling (Heidegger, 1982). The other directly enters into this process, imaginatively, for it is the other's presence that provides the grounds against which self-feeling is judged and felt. The feeling person feels the self in emotion. Self-feeling is central to an understanding of the empirical social self (James, 1890).

Cooley elaborated the looking-glass self-concept in a brief comment in "On a Remark of Dr. Holmes" that "six persons take part in every conversation between John and Thomas" (1927, p. 200). There is a real John, John's ideal John (never the real John), and Thomas's ideal John, and there are three parallel Thomases. The matter then becomes more complicated; in everyday life, 12 persons participate in every interaction, six on each side. For example, Alice, who has a new hat, meets Angela, who has a new dress. In this situation, there is the real Alice, Alice's idea of herself in her new hat, her idea of Angela's judgment of her new hat, and her idea of what Angela thinks she thinks of herself in her new hat. Also, there is Angela's actual idea of what Alice thinks of herself, and six analogous phases of Angela and her dress (Cooley, 1927).

Self-feelings move through these imputed and imagined reactions of each interactant to the other's real and imagined judgments of their social selves. Every interaction is peopled by many selves, with always more persons present in a situation than there are real bodies (Maines, 1978; Stone, 1981; Strauss, 1958). The strength of Cooley's formulation lies in its emphasis on the multiplicity of definitions, feelings, and meanings that arise in any situation in which two persons come together for interaction. Multiple awareness contexts of interaction characterize such situations (Glaser & Strauss, 1967).

The looking-glass self-concept is basic to the symbolic interactionist theory of interaction and remains central to current social psychological theorizing on the social self and on emotion. The centrality of the self and of self-processes in the study of emotional feeling and emotional expression is pivotal in current neuropsychological formulations of emotion (Pribram, 1981). Cooley's concepts of self-feeling and the looking-glass self warrant reexamination in light of this fact.

Cooley's arguments are quite compatible with more contemporary theories of the self that stress its gendered, semiotic, and performative character (see Butler, 1997; Dunn, 1998; Wiley, 1994).

SELF-MONITORING

Self-monitoring refers to an assessment procedure in which individuals are asked to notice and document target be-

haviors as they occur in natural settings. Self-monitoring is one of the most direct forms of behavioral assessment (Cone, 1978), and it is often employed when the use of trained observers is not feasible. Self-monitoring is also the most direct form of assessment available when target responses are private by nature (e.g., thoughts and feelings) or by convention (e.g., sexual behavior). In self-monitoring, recordings are made as the target behavior occurs. For this reason, self-monitored data are less vulnerable to errors or distortion that can occur when reporting information from memory. In addition to recording the occurrence of a target behavior, the self-monitor may be asked to record features of the context as well as potential consequences of the target behavior. This information is useful in designing behavioral strategies for intervention.

There are several procedures for self-monitoring. If a target behavior is fairly low in frequency, each occurrence can be recorded in an ongoing frequency count. Frequency counts may be burdensome for the self-recorder if a target behavior occurs very often. Frequently occurring behaviors might be self-recorded within predetermined time intervals (e.g., two mornings out of a week) or estimated at intervals (e.g., recording every two hours). While some information may be lost, these latter methods may produce greater compliance than would frequency counts.

When it is important to consider the amount of time spent engaged in a target behavior, the self-monitor can record the duration for each occurrence. This information is probably more precise for responses that have a more salient onset and ending, such as studying. Other activities, such as worrying, may begin with less notice. Self-recorders may be asked to estimate the starting time when they find themselves engaged in this type of target activity.

Particularly in the early stages of clinical assessment, it may be difficult to identify specific behaviors to target for change. For example, an individual might want to target anger but may not be able to specify particular responses that are disruptive or problematic. Even when target behaviors are readily identified, it is often desirable to collect as much information as possible concerning the circumstances and potential consequences associated with these behaviors. In these cases, diary formats may be preferred. Diary formats allow the self-recorder to supply more elaborate and narrative descriptions of their behavior and the environment in which it occurs. As problem areas are revealed, assessment can focus on more specific target behaviors using more structured self-monitoring forms.

Aside from its value as an assessment tool, self-monitoring appears to have beneficial treatment effects. This is because the frequency of self-monitored behaviors changes when individuals begin to self-monitor. This phenomenon is termed *reactivity* (Nelson, 1977). Reactivity poses problems for assessment in that the procedure for measurement changes the frequency of the behavior being assessed. However, these reactive behavior changes tend to benefit the client because self-monitored behaviors tend to change in desirable ways. Unwanted behaviors become less frequent when self-monitored, whereas desirable behaviors become more frequent with self-monitoring. Reactive effects are typically small and short-lived. However, they are immediate and may encourage continued investment in behavior change.

Several factors can detract from the accuracy and utility of self-monitored data. As noted earlier, the procedure involves two separate responses. The self-recorder must first notice the occurrence of the behavior and then make the necessary recording. Both responses must occur for consistent and accurate information to be collected, and problems may arise that interfere with one or both. For example, self-monitors may have difficulty noticing behaviors that are not clearly specified and defined. Alternatively, clearly defined target behaviors may be difficult to notice. For example, a person might be asked to self-record instances when they have the thought "I'm a failure." Although the thought may be clear, it may be so fleeting or ego-syntonic that the person does not notice each instance. Other factors can influence whether a noticed behavior is actually recorded. Failure to record might occur when forms are difficult to access or when target behaviors are socially unacceptable. Alternatively, highly desirable behaviors might be overrecorded. When compliance is problematic, self-recorders might complete forms all at once just before returning them to the assessor rather than collecting the data in an ongoing fashion.

Many of the aforementioned difficulties can be alleviated by implementing procedures that have been shown to enhance the accuracy of self-monitored data. These include (1) clearly defining target behaviors, (2) requiring that recordings be made immediately after the target behavior occurs, (3) providing training to self-monitors, (4) emphasizing the importance of accurate data collection and providing reinforcement for accurate data collection, (5) minimizing the number of target behaviors being monitored at one time, and (6) regularly checking the accuracy of self-monitored data and informing self-monitors that their accuracy will be checked (see Korotitsch & Nelson-Gray, 1999, for a review).

The accuracy of self-recordings can sometimes be checked through comparison with data collected by observers. For example, a spouse or roommate might occasionally collect observations to compare with self-recordings of an insomniac. For some target behaviors, other measurements can corroborate self-monitored data. For instance, regularly collected measurements of weight might be compared to self-monitored food intake in a weight reduction program.

In conclusion, self-monitoring is a widely used assessment device because of its convenience, the accuracy of collected data under conditions specified earlier, and the initial therapeutic benefits due to reactivity.

SELF-REPORT AND SELF-RATINGS

Self-report assessment methods are those in which individuals are asked to summarize their behavior and report this information retrospectively. Self-report measures include interviews, questionnaires, self-ratings, and cognitive assessment methods such as think-aloud procedures. Self-report is the most indirect method for assessing overt behavior. However, it is the most direct method available for assessing behaviors that cannot be readily observed, such as thoughts and feelings.

Interviews, questionnaires, and rating scales are the most widely used self-report methods. Interviews vary in the degree to which they are structured (confined to particular areas of inquiry) and standardized (with uniform procedures for administration and scoring). Unstructured interviews follow no predetermined order and vary in content depending on the responses and concerns that are raised. This open-ended approach is often a useful starting point in clinical assessment. In contrast, structured interviews contain specific questions that are administered in a set sequence. These interviews are generally designed for nonprofessionals to administer and are frequently used to establish a psychiatric diagnosis for research purposes. More commonly used by clinicians is the semistructured interview. These interviews also follow a format; however, they allow the interviewer to pursue additional information when necessary and demand more clinical judgment.

Questionnaires are easily administered and are highly efficient in terms of cost and time. Questionnaires can generally be divided into broad and specific types (Korotitsch & Nelson-Gray, 1999). Broad questionnaires assess general functioning in multiple life areas, multiple diagnostic categories, or multiple psychological constructs such as traits. Specific or brief questionnaires focus on particular behaviors or areas of functioning. For example, one brief questionnaire might assess recent symptoms of depression, whereas another might assess the thoughts and beliefs that are often associated with depression. Broad questionnaires provide more comprehensive information, but they require more time and resources to administer, score, and interpret. Broad questionnaires also tend to be less sensitive to small or specific changes in behavior over time. For these reasons, broad questionnaires are usually administered infrequently, such as before and after treatment. Specific questionnaires are more often used to assess ongoing behavior change throughout treatment.

Many questionnaires have available norms. They can be administered to very large groups of people, and a particular score can be compared to the population average to determine whether it falls outside of the normal range. Norms may also be used to determine whether treatment results in scores that fall closer to the average range. This information can be collected frequently and used to assess ongoing progress in treatment.

Self-ratings require respondents to generate numerical ratings of the response being assessed. For example, rather than reporting specific symptoms of anxiety, it can be rated on a scale of 1 to 7. Rating scales can be constructed for virtually any phenomenon an assessor is interested in measuring and are useful when no appropriate specific questionnaires are available. Bloom, Fischer, and Orme (1995) offer guidelines for constructing individualized self-rating scales.

Cognitive assessments require individuals to verbalize their thoughts in a particular situation. For instance, a phobic might be asked to verbalize his thoughts while approaching an airplane. Persons might be asked to verbalize thoughts continually (think-aloud), to report their most recent thought when given a cue (thought sampling), or to recall thoughts immediately after the situation (thought listing). These methods yield a wealth of information, but the data can be difficult to quantify and compare across individuals.

Self-report methods have several disadvantages. The accuracy of self-reported data can be difficult to determine. Information may be omitted, added, or distorted because of natural errors and imperfections in memory. Self-reports might also be based on personal beliefs or theories concerning the causes and stability of one's own behavior (Ross, 1989). Self-reported information can also be minimized or withheld when undesirable behaviors are being assessed. Similarly, more desirable responses may be exaggerated.

Self-report can also be influenced by response biases such as answering true to questions regardless of their content. Many broad questionnaires include scales that assess response bias and the tendency to provide inconsistent or inaccurate information. However, most brief scales cannot assess these biases. A final concern is that self-report measures must be designed with careful attention to the level

of sophistication and the clarity of questions. Inaccurate information can often be traced to misleading, complex, or ambiguous questions.

Self-report measures are widely used in psychology because they are economical, quantifiable, and easy to administer. More important, many self-report measures have published norms to aid in interpretations of a given score. They can also be used to assess subjective or private experiences that cannot be observed directly. There has been rapid proliferation of specific questionnaires over the past 20 years (Froyd, Lambert, & Froyd, 1996). An excellent resource to aid clinicians in choosing appropriate questionnaires is provided by Fischer and Corcoran (1994). A more in-depth discussion of self-report methods is provided by Korotitsch and Nelson-Gray (1999).

SEPARATION DISTRESS/ANXIETY

Distress resulting from separation from an attachment figure has been accepted as an attribute of normal infant development since the early part of this century (Bowlby, 1973; Freud, 1909/1955). Bowlby interpreted the distress that infants displayed to maternal separation as reflecting their anxiety at being left alone. Indeed, he saw fear of being left alone as the root cause of generalized human anxiety (Bowlby, 1973). In normal development, distress due to separation appears between the ages of 7 and 12 months and peaks around 15 to 18 months of age. This inverted U-shaped curve to the onset, peak, and diminution of distress to separation has been found across various cultures among which the pattern of rearing has varied considerably. For example, Fox (1977) found this pattern among infants raised on an Israeli kibbutz (where infants slept separately from their mothers and were cared for by a primary caregiver other than the mother). Barr, Konner, Bakeman, and Adamson (1991) reported a similar developmental function for infants raised among the !Kung bushmen in the Kalahari Desert, as did Kagan and Klein (1973) for infants raised in rural Guatemala. The common developmental change in separation distress across cultures most probably reflects universal changes in the infant's abilities to understand and represent its mother's disappearance from view. Thus, this behavior should not be considered as maladaptive but rather as a normative part of early development.

There are reports of individual differences in the tendency to display distress to separation. Davidson and Fox (1989), for example, reported a pattern of greater right frontal electroencephalogram (EEG) activation associated with a temperamental disposition to cry in response to maternal separation. Similar findings by Fox, Bell, and Jones (1992) suggest modest stability of frontal asymmetry over time.

Although normative changes in distress to separation find it diminishing around 18 to 24 months of age, instances of continued distress response to separation from mothers have been described in the child clinical literature. These instances were described under the heading of separation anxiety. Freud (1895/1959) first conceived of the concept of anxiety neurosis in 1895 and suggested that anxiety was a symptomatic consequence of a repressed libido. Only later, in 1926, did he begin to take note of separation anxiety. The psychoanalytic perspective viewed separation anxiety as a tendency for adults to experience apprehension after the loss of a significant other (Freud, 1926). Freud's later studies led him to conclude that anxiety was an emotion that resulted from the experience of traumatic events. Since that time, separation anxiety has been studied in a variety of contexts, including the attachment literature. It was not until the 1980s that separation anxiety was considered a discrete clinical diagnostic category. The *Diagnostic and Statistical Manual of Mental Disorders,* third edition (*DSM-III*) designated separation anxiety disorder (SAD) as one of the three anxiety disorders of childhood and adolescence (American Psychiatric Association, 1980). Current diagnostic criteria of SAD include excessive anxiety with respect to separation from an attachment figure (most commonly the mother or primary caregiver) or separation from familiar surroundings such as home.

Children experiencing SAD may exhibit both behavioral and physiological symptoms such as extreme distress, terror, hyperventilation, or heart palpitations when anticipating separation. Children with SAD seek to avoid separation from attachment figures and, not surprisingly, are most commonly referred to clinicians as a result of a hesitancy or unwillingness to attend school. Similarly, both

sleep disturbances and refusals to sleep are also characteristic of SAD.

Studies that examine comorbidity of psychiatric disorders indicate that children and adolescents with SAD are commonly diagnosed with other disorders as well. One half of children with SAD are diagnosed with other anxiety disorders, and one third are diagnosed with depression. It has been suggested that children with SAD may have become overly dependent on the attachment figure, often after a stressful life event such as illness or the loss of a loved one (Erickson, 1998). SAD occurs in approximately 2% to 4% of children and adolescents, and those with this disorder may be at increased risk for psychopathology in adulthood. Current treatment approaches to SAD include behavioral interventions, psychotherapy, and family interventions as well as psychopharmacological treatments.

The literature on childhood anxiety has recently emphasized the important influence of temperament factors (Kagan, Resnick, Clarke, Snidman, & Garcia-Coll, 1984) in this area. It has been found that the incidence of childhood anxiety disorders is greater in children who exhibit the temperamental characteristic of behavioral inhibition (Biederman et al., 1990). This characteristic, described as the tendency to withdraw from novel or social situations, may be related to separation anxiety.

Separation distress is a normative response across different caregiving and cultural contexts for infants to display distress on separation from the caregiver. This behavioral response appears during the second half of the first year of life and is no longer present by the beginning of the third year of life. The behavioral pattern is distinct and apparently unrelated to the phenomenon known as separation anxiety. Little is known currently about the etiology of separation anxiety in young children. Current research suggests that there may be a temperamental basis to withdraw from discrepancy or novelty. Such a bias may in some instances lead to the behavioral pattern known as separation anxiety in children.

SEROTONERGIC NEURONS

The serotonergic neurons are one of the diffusely organized projection systems in the central nervous system (CNS). Considerable research carried out over the past 40 years has clearly established the serotonergic system as a major neurotransmitter system subserving a number of important physiological and psychological functions. Although Page and his collaborators succeeded in the isolation and identification of serotonin (5-HT) more than five decades ago (1948) (Page 1976), the distribution of these neurons and their cell bodies in the CNS have been identified only after the availability of fluorescent histochemistry and immunocytochemical methods (1964). The distribution of serotonergic neurons and their cell bodies in the CNS was originally identified using fluorescent histochemistry

(Dahlstrom & Fuxe, 1964; Ungerstedt, 1971), and subsequently by more sensitive immunocytochemical methods. Serotonin is synthesized from the aromatic amino acid L-tryptophan into the serotonin neuron.

Distribution and Physiological Function of the Serotonergic Neuron

In the CNS, serotonergic neurons are limited to a group of brain-stem reticular formation nuclei, the raphe nuclei. Dahlstrom and Fuxe (1964) originally described nine serotonergic cell groups, which they named B1 through B9. Most of these groups are associated with the raphe nuclei and the reticular region of the lower brain stem from which they project rostro-caudally, and thus to virtually all areas of the CNS receive serotonergic inputs. The serotonergic neurons in the midbrain and pontine dorsal and median raphe project to higher brain centers: cerebral cortex, cerebellum, hippocampus, thalamus, hypothalamus, and basal ganglia. In contrast, serotonergic cell bodies in the ventral medulla, caudal pons, and pontomesencephalic reticular formation provide long descending projections to the spinal cord. The origins of the serotonergic projections to the dorsal horn are the neurons of the raphe magnus and adjacent reticular formation and are involved mainly in pain sensation. The serotonergic neurons that terminate in the ventral horn arise primarily from the raphe obscurus and raphe pallidus nuclei and facilitate motor activity. The preganglionic sympathetic neurons of the intermediolateral column in the thoracic cord also receive serotonergic input, mostly from the ventrolateral medulla, and are involved in blood pressure regulation and perhaps other autonomic functions. The pathways from the midbrain raphe to the prefrontal cortex may mediate depressive and cognitive effects of serotonin. The pathway from the midbrain raphe to basal ganglia likely underlies the role of serotonin in the pathophysiology of obsessive-compulsive disorder (OCD). This pathway also is thought to be related to the regulatory action of serotonin on locomotion. The regulatory functions of serotonin on emotions, anxiety, and memory are thought to be related by the pathway from the raphe to the limbic cortex. The pathway from midbrain raphe to hypothalamus might mediate the effects of serotonin on appetitive behaviors. Sexual function mediated by serotonin might be related to the descending pathways from the raphe to the spinal cord. Moreover, the serotonergic system has been implicated in the regulation of circadian rhythms through its actions on the suprachiasmatic nucleus (SCN). Recent data suggest that along with excitatory amino acids, serotonin may be important in the neutral pathway that mediates the transmission of photic information to the circadian system. Recently, it has been demonstrated that the serotonergic system also has a link to neuroadaptive changes that occur in substance dependence. For example, extracellular serotonin levels decreased dramatically during cocaine withdrawal.

The action of serotonergic neurons, as a whole, is complex, and it is difficult to understand how specific changes in serotonin neurotransmission affect specific behaviors or neurological functions. This issue becomes even more challenging by the molecular cloning of more than 14 serotonin receptor subtypes, each with its own expression pattern, coupling mechanism, and pharmacological profile. Moreover, serotonergic nerve terminals may contain other neurotransmitters, such as acetylcholine (ACh), noradrenaline (NE), substance-P (SP), enkephalins, thyrotropin-releasing hormone (TRH), calcitonin gene-related peptide (CGRP), and postraglandins. The physiological response to serotonergic innervation reflects the nature of the postsynaptic receptors. The 5-HT_{1B}, and 5-HT_{1D} receptors are autoreceptors, and they regulate further release of 5-HT through inhibition of adenyl cyclase. These receptors are both somatodendritic and terminal autoreceptors. The somatodendritic autoreceptors suppress cell firing and are believed to play a role in collateral inhibition among serotonergic neurons. These autoreceptors also lead to reduction in serotonin synthesis and release in the areas to which the cells project by inhibiting neuronal activity. In contrast, terminal autoreceptors are not believed to influence cell firing but instead inhibit serotonin release, and possibly also synthesis from the nerve terminals. Most serotonergic synapses are inhibitory, though some are excitatory.

The involvement of the serotonergic system in motor function in vertebrates was indicated initially by its dense axon terminal innervation of motoneurons in both the brain stem and spinal cord. Secondary motor structures, such as the basal ganglia, substantia nigra, and habenula, also receive significant serotonergic input as noted. Administration of serotonergic agonists produces a motor syndrome in rats: head shakes, hyperreactivity, tremor, hindlimb abduction, lateral head weaving, and reciprocal forepaw treading. Extracellular recordings in conjunction with microiontophoresis of serotonin onto motoneurons in the rat facial motor nucleus or in the spinal cord ventral horn showed that when serotonin interacts with excitatory influences on motoneurons, it produces a strong facilitation of neuronal activity (via 5-HT_2 receptors). Administration of serotonergic agonists directly into the trigeminal nerve in cats produced an increase in the amplitude of the electromyography (EMG) of both the masseter muscle and an externally elicited jaw-closure reflex.

Serotonergic System and Relevance to Disease and Therapy

Studies of the serotonergic system over the last few decades have brought clinical evidence suggesting that altered serotonin function is involved in the pathophysiology of depression, anxiety, and OCD. The strongest support for these comes from studies demonstrating that a variety of serotonergic drugs, especially those that block the reuptake of synaptically released serotonin into the presynaptic termi-

nal, are frequently effective in treating depression, anxiety, and OCD. Moreover, recent studies suggest that combined 5-HT_{2A}- and 5-HT_{2C}-receptor antagonists such as clozapine alleviate some of the symptoms (especially negative symptoms) of schizophrenia and that aberrant function of the serotonergic system may indeed be a major component of the disease. Moreover, alterations in serotonin uptake have been demonstrated in postmortem tissue studies in the limbic systems of schizophrenic patients. In addition, there is some evidence to suggest that there may be serotonergic dysfunction in at least some patients with anorexia nervosa. Animal studies using the motoneuron disease model (Wobbler mouse) suggested that sprouted serotonergic fibers in the cervical spinal cord could have excitotoxic effects on motoneurons and thus be causal to the loss of motoneurons (Bose & Vacca-Galloway, 1999).

SEROTONIN (5-HYDROXYTRYPTAMINE, 5-HT)

Serotonin (5-hydroxytryptamine, 5-HT) is an indoleamine neurotransmitter and hormone that has many actions in the central nervous system (CNS) and periphery. Serotonin was initially described as a hormone in the serum from clotted blood that caused vasoconstriction, hence the term serum-tonic factor, or serotonin. Serotonin was purified from blood and identified as 5-hydroxytryptamine in 1949. In 1953 serotonin was first detected in the central nervous system. The first serotonin receptors termed "D" and "M" types were characterized in guinea pig intestinal smooth muscle in 1957 (Gaddum & Picarelli, 1957). Serotonin achieved the status of neurotransmitter in 1963 when it was localized in neurons of the raphe nuclei. The first serotonin receptors in the CNS, the serotonin-1 and serotonin-2 receptors, were described in 1979, which triggered an explosion of investigation and discovery in the serotonergic system that continues unabated to the present (Peroutka & Snyder, 1979). The gene that encodes the 5-HT_{1A} receptor was the first serotonin receptor gene cloned and sequenced in 1986, which rapidly led to the identification of many new and unexpected serotonin receptors (Kobilka et al., 1987). By 1998 there were at least 15 distinct serotonin receptor types identified and grouped into seven broad families.

Serotonin is an evolutionarily old neurotransmitter. All metazoan species with organized nervous systems appear to use serotonin as a neurotransmitter. Serotonergic neurons, receptors, and serotonin-mediated behaviors have been described in the nematode *C. elegans,* fruit fly *D. melanogaster,* crayfish, mouse, rat, cat, pig, chimpanzee, and humans, among others. Serotonin has been shown to participate in many different behaviors, including feeding and satiety behaviors, mating and copulatory behaviors, nociception, circadian rhythmicity, arousal, sleep and REM sleep production, perception, temperature regulation, aggression, and seizure vulnerability.

In primates, serotonin exists in the CNS and the periphery. In humans approximately 90% of total body serotonin is in the gastrointestinal (GI) tract; 8% is in platelets; and the CNS has the remaining 1–2%. All of the serotonin in the body is synthesized de novo, as dietary serotonin is rapidly degraded in the GI tract. The biosynthetic pathway for the production of serotonin is identical in the GI tract and CNS. The amino acid tryptophan is the precursor from which serotonin is produced (Figure 1). Tryptophan is converted to 5-hydroxytryptophan (5-HTP) by tryptophan hydroxylase. This is the rate-limiting step and is dependent on the concentration of tryptophan. The 5-HTP is rapidly converted to 5-hydroxytryptamine (serotonin) by aromatic amino acid decarboxylase. The serotonin in serum is synthesized and secreted by cells in the GI tract and subsequently concentrated in the platelets. Despite its high intracellular concentrations, serotonin is not synthesized in platelets. The amount of serotonin synthesized in the CNS is controlled by the serum concentration of tryptophan (Maes et al., 1990). The serum concentration of tryptophan determines the amount that crosses the blood-brain barrier, which in turn controls the amount of serotonin synthesized in the brain (Carpenter et al., 1998).

In the brain, serotonin is synthesized in neurons of the raphe nuclei. The serotonergic cells of the raphe nuclei have axons that project widely throughout the CNS. The rostral raphe nuclei supply ascending serotonergic axons that innervate cortical and limbic structures, and the caudal raphe nuclei have descending axons that innervate the

tryptophan

5-hydroxytryptophan

serotonin (5-hydroxytryptamine)

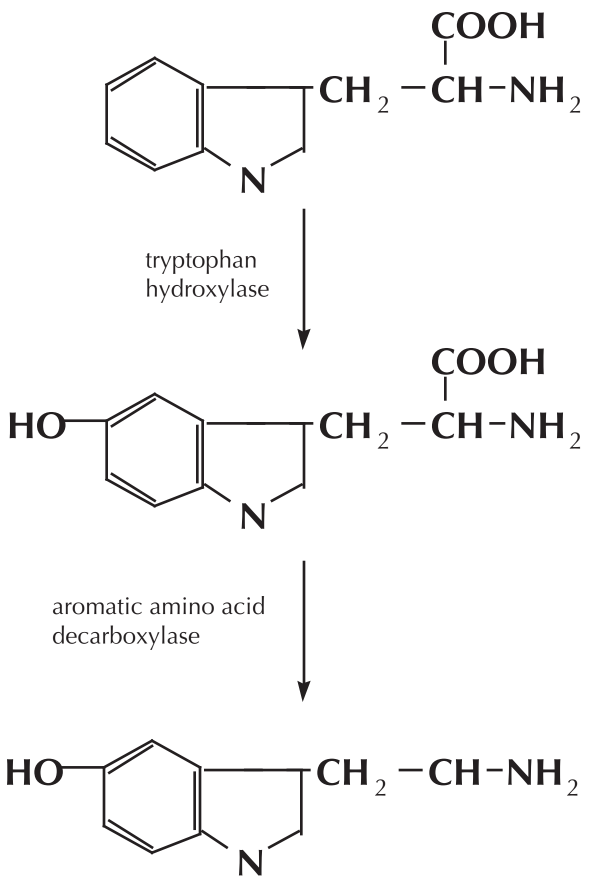

Figure 1. Biosynthetic pathway for serotonin.

spinal column. The serotonergic axons also project back onto the serotonergic cell bodies in the raphe and in this way regulate their own firing rate. The anatomical structure of the serotonergic system—with all of the transmitter being synthesized in a relatively small number of cells that in turn project widely throughout the brain—is the reason that serotonin is able to modulate so many different neurobehavioral and cognitive processes.

Depolarization of the membrane of the axon terminal causes serotonin to be released into the synapse. The serotonin diffuses across the synapse and binds to postsynaptic serotonin receptors. Transmission is terminated by the actions of the serotonin transporter (SERT) that pumps the serotonin back into the presynaptic neuron. In the CNS, the SERT is exclusively on the axon terminals of serotonergic neurons. The SERT on platelets is identical to the SERT on serotonergic neurons in the CNS (Lesch, Wolozin, Murphy, & Riederer, 1993). The SERT is the site of action of many different types of antidepressants including the specific serotonin reuptake inhibitors (SSRIs). The SERT is also the site of action of drugs of abuse including cocaine and MDMA (Ecstasy).

At least 15 different serotonin receptors have been identified and grouped into families according to molecular and pharmacological homology. The 5-HT_3 type is a ligand-gated ion channel receptor similar to the nicotinic cholinergic receptor, whereas the other serotonin receptors are 7-transmembrane, G-protein coupled receptors. Several of the serotonin receptors have been implicated in the pathophysiology of major mental illnesses. The 5-HT_{2A} receptor has been implicated in the biology of depression and schizophrenia. This receptor is the site of action of some antidepressants (trazodone, nefazodone) and of atypical antipsychotics (clozapine, olanzapine, etc.), and it is one of the sites of action of LSD and other hallucinogenic drugs. The advent of molecular biology has revealed that there are many more serotonin receptors than initially posited and that this system is much more complex than previously anticipated. The actual biological function of most of the new serotonin receptors remains obscure. Certain of the serotonin receptors, the 5-HT_{1A} and 5-HT_{1B} subtypes, also function as the perikaryal and terminal autoreceptors, respectively, further modulating the firing rate of 5HT neurons.

The serotonergic system has been hypothesized to participate in the pathophysiology of major depression, schizophrenia, anxiety disorders, impulse control disorders, sui-

cide, and substance use disorders. A large and concerted research effort has been devoted to studying the role of the serotonergic system in these conditions (Maes & Meltzer, 1995; Meltzer & Lowy, 1987). The evidence that connects the serotonergic system to these different syndromes comes both from the measurement of serotonergic function and from the actions of various pharmacological agents.

Clearly, the serotonin system is highly complex. Serotonin participates in the regulation of many different neurobehavioral and cognitive processes. Dysfunction of the serotonergic system appears to play a role in the pathophysiology of major mental illnesses. Drugs that modify serotonergic function can be both psychotherapeutic (antidepressants, antipsychotics, anxiolytics) or agents of abuse (MDMA, cocaine, LSD, etc.). Knowledge of the structure and function of the serotonergic system is in its infancy but is currently in a period of exponential expansion, and new discoveries reported with astonishing regularity.

SEVERITY OF PSYCHOSOCIAL STRESSORS SCALE

The Severity of Psychosocial Stressors Scale was developed for Axis IV of the third edition and revised third edition of the *Diagnostic and Statistical Manual of Mental Disorders.* The scale assessed precipitating stressors in mental disorders in the year prior to evaluation and formed part of the multiaxial system of modern diagnosis designed to improve the view of patients' background, symptoms, and functioning. The Severity Scale was founded on research on stressors that took place in the 1960s and 1970s, particularly the Holmes-Rahe Scale, which rated stressful life events along a hierarchy of severity.

The Severity Scale was divided into six categories of stress that ranged from no stress to catastrophic stress. Ratings were made by clinicians based on their assessment of the stress experienced by an average person. Some examples of stressors include school graduation (mild stress), job loss (moderate), unemployment (severe), severe chronic illness (extreme), and death of a child (catastrophic).

Research has distinguished the impact of time-limited events from that of more deleterious chronic stressors. For example, years of unemployment will likely be more stressful than a recent job loss. Consequently, the Severity Scale in the *DMS III-R* was rated for either acute events lasting less than six months (e.g., death in the family) or enduring conditions lasting more than six months (e.g., chronic illness). In addition, separate scales were provided for assessing stressors in adults (e.g., marital problems) and in adolescents or children (e.g., rejection by parents).

The Severity Scale was intended to help clinicians plan treatment, understand etiology better, and predict course and outcome. For treatment, information on specific stressors helps clinicians plan interventions to cope with the stress.

In terms of etiology, research on most mental disorders suggests that many factors may be involved as influences or causes. These factors may include social (external) events in combination with biologic or genetic (internal) dispositions. According to current diathesis-stress or vulnerability models of pathology, an inherent or biological vulnerability (diathesis) in an individual may be triggered by a stressful life event. Similar models have been used to elucidate the causes and outcomes of medical illnesses such as diabetes or coronary heart disease.

In terms of prognosis, theorists have suggested that acute symptoms precipitated by specific stressors that are external to the disorder may have a better prognosis than symptoms whose onset is gradual and less related to stress. For example, outcome research has distinguished good-prognosis, reactive schizophrenia (with acute onset and precipitating stress) from poor-prognosis, process schizophrenia (with gradual onset and no precipitating stress). Similar dichotomies and prognoses have been noted for mood disorders and alcoholism.

However, a review of the research (Skodol, 1991) reported several difficulties with the Severity Scale and with assessing stress in general. The scale did not seem to be widely used by clinicians. The reliability and validity of the scale were also questioned. Reliability ratings were generally low, in part due to the difficulties of rating stress. Validity was also moderate to poor for various disorders. Precipitating stress was a poor predictor of the course of illness in the psychotic disorders such as schizophrenia; the most positive predictive results occurred in depression—but not on a uniform basis. Nonetheless, significant results were generally in the hypothesized direction, with severe stressors associated with better outcomes. In addition, the prevalence of stressors varied by diagnosis. They were more likely to be found in disorders such as major depression and anxiety disorders than in schizophrenia (Skodol, 1991).

Explanations for problems with the scale included the following:

1. Clients' stressors reports were retrospective and subject to memory distortions.
2. The rating was often subjective and reflected what clinicians thought was stressful. Some clinicians focused on stressors ignored by other clinicians.
3. The background for assessment was average functioning rather than the distinct impact of the event on the individual. Critics suggest that the same stressor may have different effects on different clients.
4. The impact of multiple stressors, which often occurs, was difficult to assess. For example, a recently widowed person may also experience financial problems and social isolation.
5. The impact of continuous daily "hassles" (rather than single, major events) could not be accurately assessed. For example, the concept of *expressed emotion,* in which hostile, critical comments within families have been found significantly to impact relapse in several disorders, is difficult to assess by the Severity Scale.

Another major criticism was that only risk factors or negative stress, but not protective factors such as social supports and personal resources, were assessed. Increasingly, research has suggested that positive events, personal strengths, and social attachments may be of more import than deficits, symptoms, or negative events in predicting outcome. Positive protective factors such as social networks often mitigate the impact of stressful events.

Most important, some theorists suggest that the illness process itself may decide the protective or risk factors experienced by the individual. In other words, stressful events may be the result of the illness rather than the cause. For example, prospective, longitudinal research findings have shown that depressed individuals are more vulnerable to experiencing negative events than are nondepressed individuals (Cui & Vaillant, 1997). Individuals with severe mental disorders are more likely (because of their illness) to be unemployed or divorced or to experience other negative life events as a consequence of the illness, and these events may in turn exacerbate the illness. Conversely, some mentally healthy individuals actually seek some types of stressors (e.g., job changes) as opportunities for creativity. To a great extent, internal and external risk and protective factors are involved in complex, developmental interactions across the life span, and it is quite difficult to unravel the causes and consequences of a mental disorder.

Because of these myriad problems, the Severity Scale was dropped and replaced with a new Axis IV in the *DSM-IV:* Psychosocial and Environmental Problems. The new Axis IV is a simple notation of problems in nine possible areas such as economic problems. There are no restrictions on the number or types of events that clinicians can note, and severity ratings are not made. The new Axis IV scale in the *DSM-IV* is simpler than the Severity of Psychosocial Stressors Scale. It is hoped that the new scale will be more widely used and informative to clinicians planning treatment.

SEX BIAS IN MEASUREMENT

Bias in measurement is an issue when groups respond differently to items in an achievement, ability, or aptitude test, or in other types of measures, such as interest inventories. Sex bias in measurement is an issue when men and women respond differently to such items. The issue has particularly important implications for women's educational and occupational choices, as it has for members of minority groups.

Although the terms *bias* and *unfairness* have often been used interchangeably, the consensus among those who have studied bias seems to be to use the term bias to refer to intrinsic features of a test—its content, the construct or constructs it purports to measure, and the context within which the content is placed. *Unfairness,* however, refers to ethical questions about how the test results are used. Shepard further defines bias as occurring when two individuals with equal ability but from different groups do not have the same probability of success on a test item.

Sex bias and sex fairness in measurement have been investigated mainly with reference to interest, achievement, and aptitude tests, and to a lesser extent with reference to personality measures. Many of the differences between men and women in test performance have been attributed to differences in the socialization process—different expectations regarding early childhood behavior, interests, and achievement; exposure to different sets of experiences, including courses each was encouraged to take in school; and the stereotyping of occupations as men's work and women's work, with the latter encompassing mainly low-level, dead-end occupations in which most women workers are found.

In Interest Measurement

Until relatively recently, interest inventories—especially those with occupational scales—focused mainly on preferences for male-oriented activities. Only recently have there been attempts to build sex-balanced interest scales, with the number of items in a scale favored by one sex balanced by the number of items favored by the other sex. The National Institute of Education study of sex bias in interest measurement included guidelines for sex-fair inventories such as the reporting of scores on all scales, regardless of sex of the criterion group, to both women and men; and more sex-fair interpretation of inventory results.

In Achievement and Aptitude Testing

After the ninth grade, item context as well as content and gender balance in testing are important variables in sex differences in performance, especially in mathematics and science. Carol Dwyer related findings that in tests of verbal ability, all other things being equal, males obtained higher scores when the material was set in the context of business, science, practical affairs, mechanical principles, or mathematics. Females scored higher when the material was drawn from the arts, the humanities, or an understanding of human relations. There was no conclusive evidence as to whether these differences were the result of familiarity with the context, motivational considerations associated with the context, or some combination of the two. Tittle also described a study in which, while basic mathematical processes remained the same, when item context was manipulated experimentally to describe materials or settings more familiar to males or to females, sex differences in performance resulted. In aptitude testing, sex bias and fairness issues are perhaps best illustrated by Lee Cronbach's comments on the Armed Services Vocational Aptitude Battery. Cronbach pointed out that, among other weaknesses, the battery was poorly designed for use with women. Lack of trade and technical information (for instance, the ability to identify a carburetor) would be scored as low trade and technical aptitude, or ability to learn.

The Magnitude of Male-Female Differences

An important factor in dealing with questions of sex bias and sex fairness in measurement is the actual size of measured differences in ability. Janet Hyde describes a meta-analysis she applied to studies on verbal, quantitative, visual-spatial, and visual-analytic spatial differences between males and females. Although the differences had been described as "well established," Hyde found that they were, in fact, not large. Gender difference accounted for only 1% of the variance in verbal and quantitative ability, 4% of the variance in visual-spatial ability, and approximately 2.5% of the variance of visual-analytic spatial ability. These quantities, she concluded, were too small to account for the differences in the occupational distributions of men and women in occupations such as engineering.

A Question of Social Justice

Messick pinpointed two critical questions: (1) Is the test good as a measure of the characteristics it is interpreted to assess? (2) Should the test be used for the proposed purpose in the proposed way? The first question is concerned with the psychometric properties of the test, especially construct validity. The second is an ethical question, and to answer it the proposed use of a test must be justified in terms of social values. These questions apply not just to matters of selection or personality assessment, but to all psychological and educational measurement, including construct-based ability tests and content-sampled achievement tests.

Esther E. Diamond

SEX DIFFERENCES IN MATHEMATICS

Sex differences in mathematical aptitude favoring males have been reported for several years. Not until junior high school, however, do such sex differences become obvious. Girls then tend to excel on computational tasks, whereas boys excel on tasks requiring mathematical reasoning ability. Although the sex difference in overall mathematical reasoning ability is large, the sex difference in certain kinds of mathematics achievement is even larger. As compared with males, females complete fewer high school and college mathematics courses from a given competency level, have a lower rate of entry into quantitative fields in college for a given number of mathematics courses completed in high school, and have a lower rate of persistence in quantitative fields.

Several hypotheses have been proposed to account for these differences. The masculine-identification hypothesis states that it is necessary for one to identify psychologically with a male to have interest and ability in mathematics.

The social-reinforcement hypothesis states that sex-related differences in mathematics achievement are due, at least in part, to differential social conditioning and expectations for boys and girls.

Fennema and Sherman proposed that the sex difference in mathematical reasoning ability is simply a function of the fact that boys take more mathematics courses than do girls. Differential course taking is the result of socialization forces. Benbow and Stanley presented data that contradict this theory. They believe that some combination of endogenous and exogenous variables probably causes more boys than girls to reason well mathematically. What interactions of factors such as environment, female versus male hormones, physiologically induced differences in activity levels, and different brain-hemisphere lateralization might be responsible cannot as yet be ascertained.

SEX DIFFERENCES: DEVELOPMENTAL

The best established sex differences are in the areas of life experiences and biology. They generally are considered to cause smaller and less well-established sex differences in the psychological areas of cognitive and social-emotional characteristics.

Cognitive areas showing sex differences include verbal and mathematics achievement and visual-spatial performance; the social-emotional area showing the most consistent sex difference is that of aggression. The developmental periods during which these sex differences occur vary somewhat by area.

Girls tend to excel at verbal tasks during infancy and young childhood. The existence of sex differences in verbal achievement during the elementary school years is not as clear, although many more boys than girls have trouble learning to read. Starting in early adolescence, females tend to achieve higher average scores than males on many kinds of verbal tasks, including lower level skills such as spelling and punctuation through high-level skills such as comprehension of difficult reading material and verbal analogies. The average female advantage continues through middle age and perhaps through old age, although there is very little relevant research on the elderly. Prior to adolescence, the sexes are quite similar in mathematics achievement. Starting some time during adolescence, males on average tend to score higher than females on mathematics tests.

There are at least two major components to visual-spatial performance: analytic (including, e.g., disembedding figures from backgrounds and constructing block designs) and nonanalytic (including mental rotations and reproducing spatial relations). Prior to adolescence, the sexes are similar in performance on both components. Starting in early adolescence, males tend to have higher average scores than females in both areas. The male advantage may continue into old age, although again there is little research in this area. The sexes, however, do *not* differ in spatial performance in nonvisual modalities such as touch or hearing.

Male children, on average, are more aggressive than female children from about age 2 through adolescence and college age. This pattern is found cross-culturally. The results for adults are not as clear. A review by Ann Frodi did not find that men always display more physical aggression; she did find, however, that men reported themselves as being more aggressive and hostile than women are.

Life Experience Differences

Starting at birth, girls and boys are treated differently in many socialization areas. Adults expect boys and girls, and women and men, to differ in the physical, personality, and cognitive characteristics contained in the sex-role stereotypes, although they profess to hold similar behavioral goals for their own children regardless of sex.

Education is differentiated by sex, with increasing differentiation occurring as educational level increases. Students are exposed to sex differentiation in the various occupations found in schools. Men fill most administrative and custodial jobs and tend to teach mathematics, social studies, and science in secondary schools. Women fill most of the clerical and secretarial jobs and teach most elementary school grades and language arts in secondary schools. Although about equal percentages of females and males graduate from high school, more males are encouraged to continue, so the percentage of females continually drops as the level of the educational degree increases.

While in school, more boys than girls are encouraged and actually take the advanced mathematics and sciences courses, prerequisites to many majors in college, and more girls than boys take language courses. Correspondingly, in higher education, more females major in humanities and education, whereas more males major in scientific fields. In vocational training, women are concentrated in the domestic, health, and office staff programs, and men are enrolled in technical, agricultural, and trade-industry programs; these differences by sex lead to lower paying jobs for most women.

There also are sex differences related to family life and to work. All cultures have some division of labor by sex, usually based on mobility. Cross-culturally, men often are responsible for tasks that require travel; women usually are responsible for work that allows them to remain near home and take major child care responsibility. Both sexes perform tasks requiring strength.

There are sex differences in physical and mental health.

Males have shorter average life spans, and a higher proportion of males die prenatally and throughout life. However, women visit physicians and therapists more often. The largest sex difference for mental health problems is for depression.

Sex differences in health, both physical and mental, are mediated by marriage. Married men have lower average rates of death and illness than unmarried men. The healthiest women, however, are those who never marry.

As greater opportunities become available, some of the sex differences in life experiences are narrowing, primarily because increasingly more women are choosing to participate in activities, education, training, and jobs that have been considered culturally male appropriate. However, the gap in sex-differentiated pay scales has not narrowed; it appears to be widening.

Biological Sex Differences

Several biological areas exhibit sex differences. These include genes, hormones, brain organization, and physical characteristics. Prenatal sexual development depends on a sequence involving chromosomes, hormones, and the environment. The sequence begins with the combination of an X or Y chromosome from the father paired with an X chromosome from the mother. Testicular hormones must be present prenatally to result in a biological male, regardless of the chromosomes present; without these hormones, a biological female develops. Genetic differences related to the sex chromosomes are one possible biological influence on sex-role development and on psychological sex differences.

Differences in brain structure and function also have been theoretically implicated in psychological sex differences and sex roles. Generally, the right hemisphere of the brain is related to performance on spatial tasks and to processing several items of information concurrently while the left hemisphere is linked to performance on verbal tasks and to individual processing of information items. There may be small sex differences in brain organization, but even if they do exist, they cannot explain psychological sex differences.

Sex hormones also have been proposed as one possible biological influence. Currently, however, hormonal sex differences do not explain psychological sex differences.

There may be monthly hormonal variations associated with some sex differences in perceptual and social-emotional characteristics. Some women experience changes in activity levels, sensory thresholds, and moods related to their menstrual cycles. However, there is no evidence, despite a great deal of research, that women's menstrual cycles are related to their cognitive performances.

There are several physical sex differences; for example, on average, men are taller, heavier, and stronger than women. Girls, on average, have higher physical maturation rates than boys, and the same may be true for the maturational rate of the central nervous system. Girls reach puberty between 1½ and 2 years earlier, on average, than boys. The rate of physical maturation does seem to be related to visual-spatial skills; for both sexes, later maturers have better visual-spatial skills than do early maturers. There is no relationship between maturation rate and verbal skills.

Conclusions

Many psychologists studying the relationships among biological, life, and psychological sex differences conclude that biological sex differences do not explain psychological sex differences. Biological factors may set the potential for psychological characteristics, but the environment often overcomes the biological differences and controls the sex differences that do and do not appear in psychological characteristics.

Candace G. Schau

SEX THERAPY, FEMALE

Sex therapy starts with the correct diagnosis of the sexual dysfunction presented by the patient. Making a correct diagnosis is not an easy task due to the vague diagnoses provided by the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-IV-TR*; American Psychiatric Association [ApA], 2000), the high comorbidity of sexual dysfunctions, and the lack of age-related norms for the female sexual response. The common agreement is to look at medical etiology of the sexual complaints and then to follow with the investigation of personal and relational aspects. After this initial phase, the most liberal therapists discuss potential goals and patient expectations, which are not limited to sexual intercourse but could include skills such as communication and assertiveness or feelings of enjoyment and comfort during sexual behaviors. The techniques used in sex therapy vary according to treatment goals, dysfunction, and patient characteristics. Because sex therapy employs a symptom-oriented approach, much of the rationale is borrowed from the cognitive-behavioral school. In order to select the most appropriate form of sex therapy and therapy goals, the therapist must consider patient characteristics such as age, sexual orientation, ethnic background, and cultural expectations.

Sexual Desire Disorders

Hypoactive Sexual Desire Disorder

Women with Hypoactive Sexual Desire Disorder (HSDD) complain of a low interest in general sexual activities.

There are currently no empirically validated treatments for HSDD. Sex therapy techniques generally consist of 15 to 45 sessions of cognitive therapy aimed at restructuring thoughts or beliefs that may adversely impact sexual desire (e.g., "women should not initiate sexual activities," "sex is dirty") and to address negative underlying relationship issues. Behavioral approaches are utilized to teach patients to express intimacy and affection in both nonsexual (e.g., holding hands, hugging) and sexual ways, to incorporate new techniques into their sexual repertoire that may enhance their sexual pleasure, and to increase sexual communication. Testosterone is effective in restoring sexual desire in women with abnormally low testosterone levels (e.g., secondary to removal of the adrenal glands, bilateral removal of the ovaries, menopause).

Sexual Aversion Disorder

Defined as the avoidance of sexual genital contact with a partner, Sexual Aversion Disorder (SAD) has a high comorbidity with history of sexual abuse, vaginismus, and dyspareunia. Treatment for this condition often combines couples therapy and cognitive therapy and focuses on solving conflict areas within the couple, such as emotional differences and issues of control. Anxiety reduction techniques such as systematic desensitization are used when the aversion is accompanied by strong feelings of anxiety. Systematic desensitization consists of identifying a hierarchy of sexual activities that provoke anxiety and then pairing relaxation techniques with imagining the sexual activity. The goal is for the patient to feel relaxed while imagining each sexual activity and eventually while actually engaging in each sexual activity. Some therapists feel that, during treatment of sexual abuse survivors, trauma-related issues need to be resolved before SAD is addressed.

Arousal Disorders

Female Sexual Arousal Disorder

Female Sexual Arousal Disorder (FSAD) is operationalized as the difficulty in reaching and maintaining vaginal lubrication or genital swelling until the completion of the sexual activity (ApA, 2000). Recently, theorists have argued that diagnosis of FSAD should consider not only the physiological dimension of sexual arousal (i.e., lubrication) but the psychological experience as well. Women of all ages may experience difficulty lubricating, although it tends to be more of a problem in later life, typically after menopause. Female Sexual Arousal Disorder is generally assessed and treated in conjunction with Female Orgasmic Disorder or HSDD. To date, there are no validated treatments that focus exclusively on treating female arousal problems, although a number of pharmacological agents for enhancing vaginal engorgement and lubrication are currently under investigation. Techniques are often employed to help the patient become aware of her anxiety or her sexual turn-off thoughts, emotions, or behaviors. To help facilitate arousal, the patient is sometimes trained in the development of sexual fantasies, communication skills, sexual assertiveness, sensate focus, and the use of erotica or vibrators. Lubricants such as K-Y Jelly or Astroglide are often recommended to help compensate for decreased lubrication. Recently, the Federal Drug Administration approved a handheld battery-operated device called EROS-CTD for the treatment of FSAD. This suction device is placed over the clitoral tissue and draws blood into the genital tissue.

Orgasm Disorders

Female Orgasmic Disorder

Female Orgasmic Disorder (FOD) is defined in the *DSM-IV-TR* as the delay or absence of orgasm following a normal sexual excitement phase. The cognitive-behavioral treatment approach has received the greatest amount of empirical support for treating FOD. Reported success rates range between 88% and 90%. This therapy technique aims at reducing anxiety-producing thoughts associated with sexual activities and increasing positive behavioral experiences. The treatment is moderately short, averaging 10 to 20 sessions. The major treatment components include sensate focus, directed masturbation, and systematic desensitization. Sensate focus involves exchanging physical caresses, moving from nonsexual to increasingly sexual touching of one another's body over an assigned period of time. Directed masturbation involves a series of at-home exercises that begin with visual and tactile total body exploration and move toward increased genital stimulation with the eventual optional use of a vibrator. Directed masturbation is the technique with the best success rates, whereas systematic desensitization is particularly useful when anxiety plays a primary role in the dysfunction. Couples therapy, which focuses on enhancing intimacy and increasing communication, has also been used for the treatment of FOD, but the success rates of this approach have not been well established.

Sexual Pain Disorders

Dyspareunia

Dyspareunia refers to genital pain associated with intercourse (ApA, 2000). Vulvar vestibulitis is the most common type of premenopausal dyspareunia, whereas vulvar or vaginal atrophy is mostly reported by postmenopausal women. Women with these types of dyspareunia complain of pain in the vulvar area or anterior portion of the vagina upon penetration. The assessment of the type of dyspareunia should include information on the location, quality, intensity, time course, and meaning of the pain. The few studies that have examined treatment efficacy showed a moderate success rate of cognitive-behavioral techniques and biofeedback. The cognitive-behavioral approach includes

education and information about dyspareunia, training in progressive muscle relaxation and abdominal breathing, Kegel exercises to train the patient to identify vaginal tenseness and relaxation, use of vaginal dilators, distraction techniques to direct the patient's focus away from pain cues, communication training, and cognitive restructuring of negative thoughts. During biofeedback, the patient is instructed to contract and relax her vaginal muscles while a surface electromyographic sensor inserted in her vagina provides her with feedback on muscular tenseness.

Vaginismus

Vaginismus is the involuntary contraction of the outer third of the vagina, which impedes penetration of fingers, tampons, or penis. Sex therapy for vaginismus often consists of a form of systematic desensitization that involves instructing the woman to insert graded vaginal dilators into her vagina. The woman's control over the insertion of the dilators is an important aspect of the therapy. The role of the partner in the exercise is passive if the partner is at all present. The emotional and psychological aspects of vaginismus are approached through patient education and control. Exercises that reduce anxiety and substitute anxiety-provoking thoughts with positive sexual thoughts are sometimes used in conjunction with the behavioral techniques.

SEXUAL DESIRE

Sexual desire is commonly defined as a wish, need, or drive to seek out and/or respond to sexual activities, or the pleasurable anticipation of such activities in the future. It is an appetitive state distinct from genital arousal and sexual activity. The mechanisms underlying sexual desire are not well known, although it is frequently believed to have both biological and psychological components.

A number of biological factors are likely to play a role in sexual desire, including testosterone, serotonin, and dopamine. In humans, testosterone is the most widely studied of these to date. It has been shown that testosterone administered to hypogonadal men can restore sexual desire to normal levels. However, testosterone given to nonhypogonadal men does not consistently increase desire, and the majority of studies assessing testosterone treatment for women with low desire have not been successful. Dopamine and serotonin play a role in the sexual motivation of animals, but little research in this area has yet been conducted in humans.

The psychological components of sexual desire are believed to stem from both intrapsychic and interpersonal factors. Social influences also play a role in the expression and experience of sexual desire. The effect of the interactions between these elements on the development and manifestation of sexual desire is not clearly understood.

There are currently two disorders associated with sexual desire: hypoactive sexual desire disorder (HSDD) and sexual aversion disorder (SAD). HSDD is defined as persistent or recurrent deficiencies in sexual fantasies and desire for sexual activity, taking into account factors that affect sexual functioning, such as age and the context of a person's life. To meet the diagnostic criteria for HSDD, such a deficiency must cause marked distress or interpersonal difficulty. SAD, in contrast, is characterized by persistent or recurrent extreme aversion to, and avoidance of, almost all genital sexual contact with a partner. As with HSDD, the aversion or avoidance must cause marked distress or interpersonal difficulty. Interestingly, no diagnoses are associated with excessive, or hyperactive, sexual desire.

Current estimates suggest an annual prevalence of disorders of desire of approximately 23% in the US (Laumann, Paik, & Rosen, 1999), although some studies indicate that this figure may be significantly higher. The occurrence of desire disorders is believed to be on the rise, and dysfunctions of sexual desire are present in over 50% of couples seeking sex therapy, making them the most common problem at sex therapy clinics (Schover & LoPiccolo, 1982). In the early phase of research in this area, researchers estimated that women experienced desire disorders at twice the rate of men, but there is increasing evidence that these rates are equalizing across genders (Kaplan, 1995; Schover & LoPiccolo, 1982); some studies have found the rates in men approaching those in women.

Although very little research has been done on disorders of desire in general, the vast majority of research has focused on HSDD rather than SAD. HSDD, however, is the subject of much disagreement among researchers, including issues of prevalence, diagnostic criteria, etiology, and treatment methods. Indeed, some argue that the diagnosis itself merely pathologizes normal human variation in desire levels (i.e., low desire becomes a problem only when one's partner has a higher level of desire). Such areas of disagreement are exacerbated by the difficulty in accurately measuring levels of sexual desire. In the absence of a consensus regarding what constitutes the most salient aspects of sexual desire (e.g., frequency of sexual behavior, frequency of sexual fantasy, intensity of sexual urges, etc.), researchers frequently are in disagreement even as to how to measure sexual desire.

Despite these difficulties, research to date indicates that HSDD responds less favorably to treatment than dysfunc-

tions of orgasm or arousal and requires more treatment sessions to achieve positive results. Treatment of HSDD is complicated by the high prevalence (41%) of other comorbid sexual dysfunctions in patients with HSDD (Segraves & Segraves, 1991). Indeed, in many recurring cases of orgasm or arousal dysfunction, relapse may be due to an underlying desire disorder that was not successfully treated.

Major factors related to the development of HSDD are marital conflict, current or past depression, religious orthodoxy, and use of oral contraceptives. A number of commonly used medications (e.g., antidepressants, anticonvulsants, and antihypertensive agents) are also associated with a decrease in sexual desire (for a more complete listing of medications associated with decreased desire, see Finger, Lund, & Slagle, 1997).

A number of psychological treatments for low sexual desire have been proposed and evaluated to date. Such treatments include modified versions of standard sex therapy, marital therapy, cognitive-behavioral therapy, and orgasm consistency training. All of these treatments have shown some degree of success, although the characteristics likely to predict who will respond to which treatment have not been fully explored, and overall response in most of these studies is lower than for many other disorders. In addition, a number of medications have been evaluated in the treatment of low sexual desire, but most have either failed to show efficacy or require further examination to confirm preliminary findings. Future research is expected to expand the range of pharmacological and psychological options available for the treatment of disorders of desire.

SEXUAL DEVELOPMENT

According to Sigmund Freud's psychoanalytic theory of personality, sexuality begins in infancy (Freud, 1938). The development of sexuality is a major part of the development of personality. According to Freud, the individual passes through several psychosexual stages: oral, anal, phallic, and genital, each named for the erogenous zone that gives rise to the main libidinal cathexis of that period.

Behaviorally, puberty marks the onset of human genital sexuality. Puberty begins between approximately 10 and 14 years of age for females and between 12 and 16 years of age for males. Hypothalamic stimulation of the pituitary gland causes secretion of pituitary hormones, including those directed to the gonads (gonadotropic) and to the adrenal glands (adrenocorticotropic). These glands, in turn, secrete the hormones responsible for the physical changes at puberty: a rapid increase in growth, the development of secondary sex characteristics, and the development of the reproductive capacity. James Tanner outlined the chronological sequence of the appearance of secondary sex characteristics (often referred to as Tanner stages). In addition, the individual experiences an increase in sexual awareness and a heightening of sexual drives. Sexual activity, including kissing, petting, and even intercourse, is a frequent component of the adolescent experience.

Although intercourse is most often considered in the context of marriage, the incidence of premarital coitus has increased over the years. David Kallen (1980) reviewed the North American studies reported between 1900 and 1980 and noticed several major changes over those years:

1. *Percentage of adolescents reporting coitus.* The data clearly indicate an increase in the number of high school and college students reporting having had intercourse.
2. *Proportions of males versus females reporting coitus.* In the past, the percentage of males reporting having had coitus was higher than the percentage of females. Kallen found that this had changed. Owing to the increased percentage of females reporting coitus, the proportion for males and females was almost identical by 1980.
3. *Age at first coitus.* Coitus is being reported at an earlier age. Estimates vary from 10% to 25% of 15-year-olds reporting intercourse, with the greater percentage being males. By age 17, approximately one third report having experienced coitus, with almost no difference between the sexes.
4. *Number of partners.* There has been a growing tendency among adolescents to limit their sexual experience to one partner within a given time period.
5. *Type of relationship.* Not only are adolescents less promiscuous in terms of the number of their partners, but there is also a greater tendency to experience sex-

uality in a relationship of love and affection. This has traditionally been true for females. It now appears to be the norm for most males as well.

SEXUAL DEVIATIONS

Sexual deviations, or *paraphilias,* are psychosexual disorders characterized by sexual arousal in response to objects or situations that are not part of normative sexual arousal-activity patterns and that in varying degrees may interfere with the capacity for reciprocal affectionate sexual activity. This term simply emphasizes that the deviation (para) is in that to which the individual is attracted (philia). It encompasses a number and variety of sexual behaviors that, at this time, are sufficiently discrepant from society's norms and standards concerning sexually acceptable behavior as to be judged deviant.

In the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*) from the American Psychiatric Association paraphilias are classified as of several types: (1) preference for use of a nonhuman object for sexual arousal; (2) repetitive sexual activity with persons involving real or simulated suffering or humiliation; and (3) repetitive sexual activity with nonconsenting partners.

Traces of paraphilias are commonly found in the realm of normal sexuality. It is only when such activities become the focal point of sexual gratification, and thereby displace direct sexual behavior with a consenting adult partner, that paraphilias may be said to exist.

The causes of paraphilias are seen as psychogenic rather than biogenic and hence depend very much on the paradigm one adopts within psychopathology. For example, within the psychoanalytic paradigm, these disorders are viewed as a consequence of aberrations occurring during psychosexual development in early childhood; in the behavioristic paradigm, they are seen as unadaptive sexual behavior resulting from learning and conditioning experiences; in the humanistic paradigm, they presumably represent particular outgrowths of each individual's unique, albeit distorted, subjective world of experience.

Types of Paraphilias

What follows is a brief description of each recognized paraphilia, following the *DSM* categorization and description system.

Fetishism

Fetishism is essentially characterized by the use of nonliving objects or, less frequently, parts of the human body as the preferred or exclusive method of producing sexual excitement. These objects or body parts (called *fetishes*) are essential for sexual satisfaction in the fetishist and constitute the focal point of sexual arousal. Fetishists are almost always males. The objects involved in fetishism can be quite varied and commonly include women's underpants, shoes, stockings, and gloves; parts of the body that typically become fetishes include breasts, hair, ears, hands, and feet.

Transvestism

In the psychosexual disorder of transvestism, there is recurrent and persistent cross-dressing by a heterosexual male for the purposes of his own sexual arousal. The gamut of transvestism extends from secretive and solitary wearing of female clothes, through sexually relating to one's spouse while so attired, to appearing in public cross-dressed and accompanied by extensive involvement in a like-minded subgroup.

Zoophilia

Zoophilia is marked by the use of animals as the repeatedly preferred or exclusive method of achieving sexual excitement. The animal may serve as the object of sexual intercourse or may be trained to excite the paraphiliac sexually by means of licking or rubbing. In this disorder, the animal is preferred regardless of other available sexual outlets.

Pedophilia

Pedophilia (from the Greek, meaning "love of children") is essentially characterized by a preference for repetitive sexual activity with children. Such activity may vary in intensity and includes stroking the child's hair, holding the child close while covertly masturbating, manipulating the child's genitals, encouraging the child to manipulate one's own, and, less frequently, attempting intromission. A youngster of any age up to puberty may be the object of pedophiliac attention, and force is seldom employed.

Exhibitionism

Exhibitionism is characterized by repetitive acts of exposing one's genitals to an unsuspecting stranger for the pur-

pose of producing one's own sexual excitement. Normally no further contact is sought.

Voyeurism

Voyeurism is fundamentally characterized by the repetitive seeking out of situations in which the individual looks ("peeps") at unsuspecting women who are either naked, undressing, or engaging in sexual activity. Voyeurs, almost always males, derive intense sexual excitement from their peeping behavior. They usually either masturbate to orgasm during the voyeuristic activity or immediately afterward in response to the scene witnessed. Further sexual contact with the observed woman (usually a stranger) is rarely sought, and most voyeurs, like exhibitionists, are not physically dangerous.

Sexual Sadism

The widely used term *sadism* derives from the infamous Marquis de Sade, who, for erotic purposes, perpetrated such cruelty on his victims that he eventually was committed as insane. Sexual sadism refers to a disorder essentially characterized by the infliction of physical or psychological suffering on another person as a method of stimulating one's own sexual excitement and orgasm. Moreover, persistent sexually stimulating fantasies of this nature are also experienced by the individual. In some instances, the sadistic activities function as stimulants in building up to sexual relations, while in others the sadistic practices alone are sufficient for complete sexual gratification. Although the partners of sadists may be consenting or nonconsenting, the majority of sadistic behavior seems to occur in a relationship with a willing partner.

Sexual Masochism

The essential feature of sexual masochism is sexual excitement produced in an individual by his or her own suffering. That is, in this disorder the preferred or exclusive means of achieving sexual gratification is being humiliated, bound, beaten, whipped, or otherwise made to suffer. Such situations may be sufficient in themselves for full sexual gratification, or they may be a necessary prelude to direct sexual behavior, such as intercourse. Like sadism, then, masochism essentially involves suffering; unlike sadism, the suffering here is inflicted on oneself rather than on others.

Atypical Paraphilia

In the *DSM* atypical paraphilia is a residual category for individuals with paraphilias that cannot be classified in any of the other categories. These disorders include coprophilia (feces), frotteurism (rubbing), klismaphilia (enema), mysophilia (filth), necrophilia (corpse), telephone scatologia (lewdness), and urophilia (urine).

SEXUAL HARASSMENT

The United States government decided that employees have a right to feel free from discrimination while at work, and the statute that speaks to this right is Title VII of the Civil Rights Act of 1984. This law prohibits discrimination on the basis of "race, color, religion, sex, and national origin." Sexual harassment is considered to be a form of discrimination.

Definition of Sexual Harassment

Several components make up the definition of sexual harassment. First, to be considered *sexual* harassment, the conduct involved must be sexual in some way. However, this can include innuendos, jokes, pictures, leering, gestures, or other types of sexual behaviors that do not involve actual physical contact. A second component of the definition involves the recipient's perception of the sexual conduct as unwelcome. Many people meet their future mates at work, so coworkers may date, flirt, or behave in a sexual manner with one another. However, this behavior is not considered sexual harassment if both people deem it to be consensual. The sexual conduct must be unwelcome in order to constitute harassment.

The third component of the definition is that the conduct is committed or permitted by a person who is in a position of authority. Although the perpetrator of sexual harassment can be a supervisor or a coworker, the responsibility for preventing sexual harassment in the workplace is placed on the employer or supervisor. In fact, if a visitor to a business behaves in a sexually inappropriate manner, the employer can be held accountable if he or she had some knowledge of the risk and did not take adequate steps to create a safe work environment.

The reasonable-person rule comprises the fourth component to the definition of sexual harassment. The U.S. Equal Employment Opportunity Commission (EEOC) was created to develop the guidelines for interpreting Title VII and investigate violations. However, the EEOC guidelines are strongly influenced by judgments made by the federal courts, including the U.S. Supreme Court. For many years after Title VII was passed, the courts used the reasonable-

person standard to evaluate whether certain sexual conduct was unreasonable. This standard changed for several years, between 1988 and 1991, when federal judges indicated that what is reasonable to a male may not be reasonable to a female employee. Accordingly, the EEOC recommended that questionable conduct should be judged from the viewpoint of the female employee. This standard was changed again in the early 1990s when the EEOC returned to using the reasonable-person standard. Many courts have followed suit, but final decisions are made on a case-by-case basis.

The final component to the definition of sexual harassment involves how the unwelcome sexual conduct impacts the employee's job. A person's job can be affected by sexual harassment in three ways: The employee's ability to fulfill job requirements can be hampered by the unwelcome sexual conduct; his or her opportunities for career advancement can be impeded; or the sexual harassment may create what is called a hostile work environment.

Types of Sexual Harassment

Most sexual harassment cases can be categorized as either *quid pro quo* or *hostile work environment.* Quid pro quo cases are those in which the harasser either directly or indirectly conveys that the person's job is at stake, that career advancement will be jeopardized, or that the employee will suffer some type of penalty for refusing to respond to the sexual conduct. In contrast, hostile work environment occurs when the unwelcome sexual conduct produces a work atmosphere that the victim perceives to be antagonistic, intimidating, or hostile. In either type of sexual harassment, the perpetrator never has to state that the victim will suffer negative consequences for noncompliance. These outcomes are either implied or perceived. The results of a large, national telephone survey of women demonstrated that only one in six harassers ever explicitly states that the victim will experience employment ramifications for noncompliance.

A woman or a man can perpetrate sexual harassment, and the victim can be either gender. In cases where the perpetrator and victim are of the same gender, the victim no longer needs to prove that the harasser is homosexual. In other words, heterosexuals can still commit sexual harassment against someone of the same gender. In these instances, the sexual conduct may be used to make the harasser feel powerful, and he or she may not even feel sexually aroused by the situation.

As a result of a U.S. Supreme Court ruling, victims of sexual harassment no longer have to prove that they have been damaged in some way—physically, economically, or psychologically—by the sexual harassment. However, there is evidence that female victims of sexual harassment are more likely to meet criteria for major depression and posttraumatic stress disorder during their lifetime than are women who have never experienced sexual harassment.

Responses to Sexual Harassment

There are several responses that a victim of sexual harassment can exhibit. Many victims initially try to ignore the unwelcome sexual conduct, particularly if it is not physical (e.g., leering, gestures, jokes). About three quarters of sexual harassment victims will ask the perpetrator to stop the harassing behavior; unfortunately, however, a majority of harassers continue. Furthermore, there is some evidence that about one in four harassers may take action against the victim as a result of being asked to cease their behavior.

Because people perceive words and behaviors differently, pointing out the offensive behavior and requesting that it stop are recommended in situations where the victim does not have safety concerns. Documenting the unwelcome sexual conduct is also recommended and should include detailed descriptions of the conduct, exact times and dates when it occurred, and who may have witnessed it. If a company has a sexual harassment policy, the employee can follow the rules outlined in that policy. Telling a supervisor about the sexual harassment enables the employer to take necessary action to remedy the situation and once again create a safe work environment. Because the employer is held accountable for sexual harassment, arming the employer with detailed information empowers both the victim and the authorities.

If a victim of sexual harassment chooses to file a claim with the EEOC, he or she must file within 180 days of the last incident of sexual harassment, and the company must have at least 15 employees. The EEOC can provide a right to sue letter to be used in civil litigation. An employee who is being sexually harassed can also file a claim under the state fair employment practice (FEP) statutes. However, victims' identities are not protected in FEP claims like they are with EEOC claims. FEP laws also vary from state to state, whereas the EEOC falls under the federal umbrella.

Summary

Sexual harassment involves unwelcome sexual conduct that is committed or permitted by a person in a position of authority that can lead to perceived or real negative work consequences or creates a hostile work environment. The harasser may be a supervisor or coworker, male or female, and of the opposite or same sex as the victim. Asking the perpetrator of sexual harassment to stop usually does not lead to the cessation of the harassment, and employees are encouraged to follow their company's sexual harassment policy and notify a person in a position of authority who can

help restore a safe work environment. Victims of sexual harassment are at risk for major depression and posttraumatic stress disorder, although proving that a victim suffered psychological consequences is no longer required as evidence that sexual harassment occurred. Victims of sexual harassment can contact the EEOC for information and guidance and to file complaints within 180 days of the last incident of harassment.

SEXUAL INTERCOURSE, HUMAN

Human sexual intercourse, or coitus, is one of the most common sexual outlets among adults. Although it is usually considered in the context of marriage, premarital and extramarital intercourse are also widely practiced. Adolescents appear to be engaging in sexual intercourse more frequently than in the past. Although cultures differ widely in their acceptance of premarital intercourse, U.S. customs have been traditionally more restrictive than most.

Sexual intercourse generally refers to penile penetration of the vagina, the most common sexual expression between opposite-sexed partners practiced in the United States. In a large national survey study of over 3,000 participants, Laumann, Gagnon, Michael, and Michaels (1994) found that 95% of men and 97% of women reported that they had experienced vaginal intercourse. Other sexual techniques with opposite-sex partners include anal intercourse and oral sex (both cunnilingus, i.e., male mouth on female genitalia, and fellatio, i.e., female mouth on male genitalia). These sexual expressions are far less common, however, than vaginal intercourse both in terms of life incidence and most recent experience.

In practice, North American sexual customs have changed from a double standard in which sexual intercourse was permissible for males but not for females to a standard of permissiveness with affection. Many adolescents and adults, however, still adhere to a standard of abstinence until marriage as an ideal. Despite that, the age at first intercourse has steadily declined over the past 40 years, according to Laumann et al. (1994).

Cultures also differ in the preferred manner of experiencing intercourse. Whereas American partners prefer a face-to-face, man-above position, this practice is by no means a universal preference. In *Human Sexuality,* McCary (1967) noted that whereas 70% of American males had never copulated in any other manner, this technique was relatively rare in other cultures. As do many authors of texts and manuals on human sexuality, McCary describes alternative patterns with their respective physiological and psychological advantages.

SEXUAL ORIENTATION, ROOTS OF

No one is certain why a majority of individuals are heterosexual and a minority are homosexual or why some of us accept the sex in which we are born and others do not. Most clues, however, point to genetic and endocrine forces interacting with social experiences. These biological factors set a bias with which the individual meets society to effect sexual orientation and sexual identity. Not everyone, however, sees biology as playing so strong a role.

The strongest evidence that sexual orientation has a biological basis comes from studies of human families and twins. Classical studies in this area were done in the 1950s with identical and fraternal male twin pairs in which at least one of the twins in each pair, at the onset of the study, admitted to homosexual behavior. Among these twins, it was found that if one of the identical twins was homosexual, so, too, was his brother. Among the nonidentical brothers, on the other hand, the twins were essentially similar to the general male population.

A slew of studies soon followed that reported identical twins not concordant for homosexuality, and theories that held to a genetic component to homosexuality lost support. Alfred Kinsey as well as Masters and Johnson also argued that homosexuality was of social rather than biological origin.

Subsequent research since the 1980s, however, supports a biological component to sexual orientation. In one set of studies, almost 200 families were examined in which at least one member was openly known to be homosexual. A set of heterosexual index individuals were controls. The investigators then inquired of the sexual orientation of all siblings. Their basic finding was that if a family contained one son who was homosexual, 20% to 25% of his brothers would also be homosexual. If an index brother was heterosexual, the chance of other brothers being homosexual was only 4% to 6%. Another study reported findings of behavioral concordance among six pairs of monozygotic twins reared apart in which at least one member of each pair was homosexually active. More recent research strongly supported these original

findings. One such study of 110 pairs of twins found that half of identical twin brothers of self-identified homosexual men were also homosexual, compared with 22% of fraternal twins and 11% of unrelated adoptive brothers. Separate and additional research in the United States and Australia similarly found a high concordance for homosexuality among identical twins. These data indicate that genetic makeup has a significant influence on male sexual orientation. Among females, studies also show a link between genetics and orientation but not as strong as that for the males.

New avenues of research are being followed. One line of investigation finds a birth order effect relative to male homosexuality. Younger brothers are more likely to be androphilic than older brothers. Some type of immune response within the mother during pregnancy, with later male children, has been hypothesized. Another type of research has reported results that are conflicting. Investigators have consistently found that fingerprint patterns significantly differ between males and females. These characteristics are being probed to see if they correlate with sexual orientation. Some studies find the effect, while others do not. Because these patterns are formed before birth, social forces cannot be involved.

Research has also found that certain brain structures differ between heterosexuals and homosexuals. Dutch researchers found that a region of the brain called the suprachiasmatic nucleus is much larger in androphilic than in gynecophilic males. American investigators have found a region of the hypothalamus (INS 3) that is smaller in androphilic males and women than in gynecophilic males. The brains of lesbians have yet to be examined. Others also have found that different areas of the brain differ between men and women. Such structural differences may yet be found to differ among heterosexual and homosexual individuals.

Many studies document instances in which biological bases for heterosexuality and maleness override the social conditioning of rearing males as girls. In probably the best known case, the John/Joan story, a male infant whose penis had been accidentally burned off was raised as a girl (pseudonym Joan). Despite efforts by family and therapists to have Joan adjust to this situation, she rebelled. As soon as this child was able, he switched to living as a male (pseudonym John) and sought surgery to remove his breasts—induced by physician-administered estrogen—and fashion a penis. John developed as a gynecophilic male with strong manly mannerisms and attitudes. He now lives as a married male with adopted children.

Research from other cultures also is instructive. Among a group of individuals in the Dominican Republic, it was found, due to a genetic quirk, that some males were born with female-appearing genitalia. Their parents raised them as girls. However, this same genetic condition resulted in a penis and scrotum developing by puberty. Despite having been raised as girls from birth, 17 of 18 of these teenagers then switched, on their own, to life as the heterosexual males they felt themselves to be. Males born in Gaza and raised as girls (with a similar but different genetic condition) were found to desire similarly to live as males. Other investigators in other parts of the world found somewhat the same. For these latter cases, some argue that the parents knew in advance they would be switching their children's gender so that these subjects do not constitute a true test of the nature-nurture issue. This can be true for some of the latter cases studied, but it does not hold for the early cases before their association with modern medicine. Nature seems to have a strong influence.

These findings are not to say that culture and society are not influential in shaping an individual's sexual orientation. However, these social and cultural forces seem to be superimposed on certain biological givens. In so doing, they modify the frequency and character of the demonstrated behaviors but not the impulse for the behavior.

SEXUAL SUBCULTURES

The term *homosexual* refers to private behavior, the term *gay* to public behavior and association with a subculture. Although the majority of homosexually oriented individuals are probably closed about their activities, others are open about their sexual preferences and often are identified by various mannerisms and activities. These observable traits may be effeminate ones by males or masculine ones by females. These may be natural expressions of the self or part of highly formalized codes that signal group identity. Many of the social cues used to signal erotic interest are the same for homosexuals and heterosexuals (e.g., eye contact, use of double entendres). Yet for male and female homosexuals moving in a primarily heterosexual (*straight*) and often hostile world, certain clues are useful: subtle uses of voice tone, stance, mannerisms, and code words, and frequenting known contact places such as bars, galleries, coffee and bath houses, or park areas.

The visibility and social acceptance of homosexual activity has varied with time and place. There is probably more visibility and acceptance of homosexuality and other sexual preferences in the West today than ever before. There is no evidence, however, that same-sex behavior or other activities are any more or less prevalent than in the past. Transsexuality became more visible as surgical techniques become increasingly available; transsexual people could turn wish to reality. Intersexuality has only in the last decade or so opened up as a publicly recognized phenomenon even though it is as ancient as life itself.

Ambiphilic behavior also came to be more openly discussed in the 1990s than in the past. There is again no evidence that it is any more prevalent than at any other prior

era. Bisexuals appear more often to congregate with homosexuals than heterosexuals but see themselves, and might well be considered, in a category of their own. As lesbians have done before them, they call for recognition as separate from homosexuals in general, with particular group needs and interests.

Women who prefer same-sex erotic and love-activities, exclusively or occasionally, used to be called *romantic friends* in Victorian times. Even more so than males, they were a secret minority in the West whose visibility became public only after World War II. Into the 1970s they were lumped with males as female homosexuals or female gays. Later, for political reasons they preferred to be called lesbians because it gave them identity as a group. They often prefer that the term *gay* refer only to males. Although many common needs exist among male and female homosexuals, lesbians have some special needs. In particular, they feel most strongly about not being stereotyped. As with individuals of any other grouping, they can be feminine or macho, conservative or liberal, devout or atheist, uninterested in orgasm or orgasm-driven, promiscuous or monogamous, in the closet or out of it, and attractive or plain. Their motivations or reasons for identifying with the lesbian community are often broader than those for male homosexuals. Some women will engage in same-sex activity for (feminist) political reasons, whereas comparable activity is nonexistent among males. For political and strategic reasons, however, groups of lesbians, gays, bisexuals, and transgendered individuals often come together. They identify the group with a label such as "Hawaii LGBT."

It should be simultaneously mentioned that there are many individuals who have sex with members of their own sex but do not consider themselves homosexual, lesbian, or gay or associate with the gay scene. For this reason, as well as others, those involved with AIDS research, for example, use the designation "males who have sex with men" (MSM) instead of referring to homosexual behaviors.

In any culture, clothes are symbols of maleness or femaleness and mark affiliation or separateness. Clothes serve in obvious ways to keep the genders distinct and readily identifiable. There is demonstrably a great deal of psychic and social investment in clothing, and many people are disturbed that others do not keep inviolate the clothes, and thus group identity, that society expects and prefers. For children younger than six, or somewhat older, it is often clothing (or hair style or occupation of adults) rather than genitals that determines their understanding of gender and serves as their means of identifying man from woman. In this regard, it is significant to mention cross-dressing subcultures, of which there are many. Most often, cross-dressing activities are done in private. The motivations for cross-dressing are many. This might be for comfort when the individuals claim to feel relaxation in dressing in clothes of the other gender. Some claim that cross-dressing allows them to express their full personality, incorporating aspects of both genders. For such persons, homosexual activity or fantasies are not necessarily part of the exercise. In other cases, however, there is a definite heterosexual or homosexual erotic component to the activity. The cross-dressed individual might be thus aroused and follow the activity with masturbation, intercourse, or another activity ranging from autoasphyxia to sadomasochistic play. Certainly, cross-dressing behavior might be associated with a desire totally to shift gender. This would be the typical story for transsexuals.

In most democratic societies, from the United States and Great Britain and Japan to European and Latin American countries, social groups exist to accommodate all the subcultures mentioned and many others as well. It is probably true to say that almost every paraphilia or sex-associated interest or fetish has a social group associated with it. These might be quite open in the culture or very much hidden. Aside from those mentioned already, there are social groups for sadomasochistic activities, mate or partner exchanges (wife swapping), social nudism, and so on. Any good Web search will uncover several social groups to meet the desires of most anyone.

SEXUALITY: ORIENTATION, IDENTITY, AND GENDER

Sexual orientation refers to the erotic-love-affectional partners a person prefers. In lay usage one often speaks of a person as a homosexual or heterosexual, and indeed people often refer to themselves the same way. Such usage, however, often links together those whose regular sexual partners are of the same sex with those whose same-sex encounters are rare. The terms heterosexual, homosexual, and bisexual are better used as adjectives, not nouns, and are better applied to behaviors, not people. The term *homosexual* is best reserved for those whose sexual activities are exclusively or almost exclusively with members of the same sex, the term *heterosexual* for those whose erotic companions are always or almost always with the opposite sex, and the term *bisexual* for those with more or less regular sexual activities with members of either sex.

Lately Diamond encourages the terms *androphilic, gynecophilic,* and *ambiphilic* to describe the sexual-erotic partners one prefers (andro = male; gyneco = female, ambi = both; philic = to love). Such terms obviate the need to define specifically the sex of the subject and focus on the desired partner. This usage is particularly advantageous when discussing transsexual or intersexed individuals. These latter terms also do not carry the social weight of the former ones.

To sexologists and others that study sex, *sexual identity* refers to the way one views the self as a male or female. One's inner conviction of sexual identity may or may not mirror the outward physical appearance, the gender role society imposes, or the role one develops and prefers. These distinctions are crucial particularly in regard to transsexualism and the intersexed. In the real world, the *transsexual,* like others, is identified in terms of overt sexual anatomy. Transsexuals are reared as society views them. Nevertheless, the self-image of transsexuals is of the opposite sex. Their physical realities are in conflict with their mind's image. *Gender identity* is the recognition of how one is viewed within society. The female-to-male (FtM) transsexual has the sexual identity of a male but recognizes that society treats her as a woman. She strives to reconcile the two identities with masculinizing surgery and lifestyle. For a male-to-female (MtF) transsexual the situation is reversed. For transsexuals it is more satisfactory to change the body than the mind.

An *intersexed* individual is one born with physical characteristics that are both male and female. For example, an individual can be XX in chromosomal configuration but have a male-like phallus; another individual might have XY chromosomes and have a vagina. Intersexed individuals might identify as female, male, or intersexed.

Sexual identity is an aspect of life tangentially related to sexual orientation. Any individual, even if transsexual or intersexed, may be androphilic, gynecophilic, or ambiphilic. In everyday terms, anybody may identify as homosexual or see their identity as heterosexual. Similarly, people might identify themselves as transsexuals or intersexed. This use of the terms is affiliative: It is as if one might identify as an American or a Unitarian.

One's *gender, gender pattern,* or *gender role* is different, though related, to the concept of orientation and identity. Gender and gender role refer to society's idea of how boys and girls or men and women are expected to behave and be treated. A sex role is the acting out of one's biological predisposition or the manifestation of society's imposition. The terms *boys* and *girls* and *men* and *women* are social terms; the terms *male* and *female* are biological terms. A male may be raised as a boy but grow to live as a woman and vice versa. For most people, their identity, orientation, and gender are in concert. The typical male sees himself as such, has masculine behavior patterns (a combination of biologically and socially determined behaviors), is treated as a male by society, and prefers to have sexual interactions with females. The typical female sees herself as such. She has feminine behavior patterns (also a combination of biologically and socially determined behaviors), is treated as a female by society, and prefers to have sexual interactions with males. Variations occur when an individual prefers erotic relations with one of the same sex or when a male sees himself as a female (male transsexual), a female sees herself as a male (female transsexual), or an intersexed individual elects to follow aspects of androgynous life.

It is thus obvious that one's sexual profile as a male or female or man or woman is not necessarily simple. At least five components are needed to describe adequately a person in sex and gender. A mnemonic for recalling these is PRIMO: gender Patterns (roles), Orientation, and Identity have been discussed. *Mechanisms* are inherent physiological factors that structure significant features of erotic life. Well-known and sexually obvious mechanisms are male penile erection and female lubrication as functions of erotic arousal. *Reproduction,* both in its basic physiology and all its social and cultural features, is another main component of sexuality.

A typical gynecophilic male sees himself as a male, lives as a man, enjoys his penis, and prefers erotic relations with a woman. An androphilic male also sees himself as a male, lives as a man, and also enjoys his penis but prefers to have erotic relations with another man. In contrast, the male transsexual sees himself as a female, prefers to live as a woman, wants to have his penis removed and replaced with a vulva and vagina, and wants to have breasts. As often as not, he will be androphilic and view this as a heterosexual encounter because he sees himself as a female. No typical male homosexual would want to have his penis removed and replaced with a vagina: This, however, is the frequent desire of the male transsexual. For a female transsexual the converse is true. Although she may not always opt to have a penis and scrotum constructed to replace her vagina and labia, she usually wants her breasts removed and her periods to cease because they are constant and visible reminders of what she feels she is not. Intersexed individuals are of such great variety that no consistent description would hold for all.

SHAM RAGE

There has been much research in the area of sham rage, which has been characterized as an affective and pathological aggressive state. Attempts to understand better the anatomical substrate associated with sham rage, using primarily stimulation and ablation procedures throughout the entire limbic system, have unfortunately produced somewhat confusing results. Research on sham rage has often yielded contradictory data, perhaps because of the diffuse interconnections between the limbic system and other

brain areas, which themselves may be partly responsible for the complex emotional and motoric behavior associated with the disorder. Moreover, the use of different species in the investigation of sham rage has produced varied results, further muddling our understanding of this behavioral and emotional phenomenon. The present description outlines the most consistent neurological findings of sham rage in both animals and humans. The major connections from the limbic system, and the amygdala in particular, to other brain regions are then elucidated. In conclusion, a general model of hostility and sham rage is presented.

One of the primary findings in the study of animal rage is that temporal lobe ablation produces placidity, whereas temporal region arousal generally yields hostility. Experiments conducted in the 1930s produced data supporting this notion, finding that bilateral fronto-temporal ablation tamed previously aggressive rhesus monkeys. Further development for this concept occurred in the late 1950s and early 1960s, when researchers found that the ablation of the amygdaloid bodies (within the temporal lobe) promoted pacification in the Norway rat. Around the same time, researchers demonstrated that temporal lobe stimulation produced a rage-like response in conjunction with the intensification of negative affective behaviors. It has been generally accepted that the amygdaloid bodies play a particularly important role in the production of hostile behavior.

Animal research also indicates that septal arousal, as opposed to arousal of the amygdaloid body, may play an integral role in producing emotional calming and placidity. Some of the earliest research demonstrated that septal lesions caused sham rage, whereas septal stimulation yielded an apparently pleasant state. Septum stimulation was apparently rewarding, as animals continuously pressed a lever to stimulate their own septal regions.

Researchers generally support the notion that humans experience similar emotional and behavioral sequalae as animals from septal and amygdaloid dysfunction. For example, using noninvasive procedures, amygdaloid lesions in humans have been found to produce a placid response. Moreover, partial complex seizures within the temporal lobes have been documented occasionally to cause nonpurposeful violence and, though hotly contested, perhaps purposefully directed rage. Irrespective of a temporal lobe seizure's sequelae, stereotactic amygdaloidectomy has been found to decrease rage behavior in highly aggressive patients who have a seizure disorder. Moreover, as in animals, human septal dysfunction (from tumor) has been associated with irritability and rage.

Given the extensive interconnections of the amygdala with other brain structures that promote the fight-or-flight response, it is easy to understand the amygdala's role in sham rage. Specifically, amygdaloid activation promotes arousal (and behavioral output) of the lateral hypothalamus (producing tachycardia, galvanic skin response increase, pupil dilation, and blood pressure elevation), parabrachial nucleus (panting, respiratory distress), ventral tegmental area, locus coeruleus, dorsal lateral tegmental nucleus (behavioral electroencephalographic arousal, increased vigilence), and periventricular nucleus (corticosteroid release for the stress response). Thus, amygdaloid hyperactivation may not produce sham rage itself. Rather, it initiates a chain of neuroanatomical events that produce their own cognitive, emotional, and behavioral features. When summated, these features equate to sham rage. Similarly, amygdaloid body lesion produces the reverse pattern of behavior (placidity).

Both data and theory have supported the notion that the hypothalamus is integral to rage production. The septum and amygdala are both extensively interconnected with the hypothalamus, thus providing neuroanatomical support for a hypothalamic role in rage. Indeed, lesion studies with cats and case studies with humans support the role of the hypothalamus in rage production. It is thus proposed that the hypothalamus acts to balance the septum and amygdaloid regions to promote normal levels of hostility and that prefrontal and temporal regions also interact (via the inhibitory uncinate tract) to yield stable aggression levels. Given these theories, it would then be expected that lesion of the septum or hypothalamus or stimulation of the amygdaloid bodies may produce sham rage.

SHAMANISM

Shamanism may be humankind's most enduring healing tradition, having survived for tens of thousands of years on all continents except Antarctica. Because of their psychological techniques, shamans are sometimes described as the world's first psychologists and psychotherapists. Shamans are often confused with other healing practitioners such as priests, mediums, and witch doctors, and do in fact often fill these roles. However, they can be distinguished and defined as practitioners whose activities include a method of gaining information by voluntarily entering alternate states of consciousness, in which they experience themselves, or their spirits, traveling to other realms at will, and there obtaining information and power with which to benefit others.

There has been considerable confusion over the psychological status of shamans, who have been dismissed as tricksters, pathologized as psychologically disturbed, or elevated to sainthood. Until recently the conventional academic view was that shamans and shamanism were the products of primitive or pathological minds, and diagnoses such as hysterical epileptic, psychotic, and schizophrenic

were applied liberally. However, this appears to reflect a number of unfortunate biases, including ethnocentrism, the well-known tendency to dismiss or diagnose unfamiliar experiences, the confusion of clinic and culture, the pathologizing tendency of psychoanalysis, and lack of researchers' personal familiarity with shamanic experiences and alternate states. Several studies describe shamans as being exceptionally healthy, effective, and powerful and many of their experiences and states as being carefully cultivated, culturally valued, and phenomenologically distinct.

The opposite view, that shamans are virtual saints whose experiences and states of consciousness are equivalent to those of advanced yogis and meditators, has recently become widespread in the popular culture. However, although many shamans are compassionate, some are wiley tricksters, and phenomenological analyses show that shamanic experiences are quite distinct from yogic and meditative ones.

Shamanic techniques include both physical and psychological approaches. One of their central and defining techniques is the shamanic journey. Here they enter an alternate state of consciousness, experience leaving their body and roaming as free spirits throughout the universe, and acquire knowledge and power (especially from other spirits) to bring back to their tribespeople. To obtain the requisite state of consciousness, shamans employ preparatory ritual and ascetic practices and then use combinations of ritual, rhythm (usually involving drums, rattles, singing, and dancing), and occasionally psychedelics. Psychedelics, such as ayahuasca in South America, are used in a sacred context for spiritual, diagnostic, or therapeutic purposes. As such, they are culturally valued and have apparently not been subject to misuse or abuse.

Shamans are ontological realists, meaning that they take the realms they visit and the spirits they meet to be objective, independent realities. Contemporary psychological perspectives might view them as mind-created images akin to guided imagery, guided visualizations, or Jung's active imagination. Whatever one's philosophical interpretation, it seems that shamans can intuitively access valuable diagnostic, therapeutic, and life wisdom from their experiences.

Other techniques include physicalisms of diet, massage, manipulation, and herbal treatments (which are currently being researched by ethnobotanists). Psychological diagnostic techniques include an early projection test using a rock and assessment of muscle tension as an index of conflict.

Psychotherapeutic approaches include specific techniques such as confession, catharsis, music, ritual, and trance induction. Nonspecific approaches include expectation, attention, suggestion, and group support. The entire therapeutic process occurs within what Jerome Frank calls a shared healing myth, meaning that both shaman and patient share beliefs concerning the nature, cause, and appropriate means for curing illness. The net effect of all these factors probably includes a strong placebo effect.

From the shaman's perspective, the therapeutic factors are spiritual or psychic as much as, or more than, psychological or physical. Although research and meta-analysis evidence for some psi phenomena appear to be becoming more solid, studies of psi in shamans have been inconclusive, and most researchers decide the matter according to their personal belief systems. Whatever one's belief, however, it is clear that shamanism represents an extraordinarily widespread and enduring tradition of psychological and medical practices that have been used across centuries and cultures.

SHARING OF BELIEFS IN GROUPS

Many of an individual's beliefs are shared by few individuals, by members of a small group, by members of a society, or even by the majority of human beings. Shared beliefs are usually acquired from external sources and are disseminated through interpersonal communication networks or via societal mechanisms of communication.

Of special importance for group life are those shared beliefs that play a determinative role in the development of social identity, solidarity, interdependence, unity, and coordination of group activity—all are necessary conditions for the functioning of social systems. These beliefs are formed on the basis of common experiences of group members and exposure to the same channels of communication. Furthermore, groups not only form these shared beliefs but also make special effort to disseminate them among group members and maintain them.

From the perspective of a century, it can be noted that although the interest in shared beliefs is as long as the history of modern psychology, it has never been a major focus of study, except at the beginning of the emerging discipline. Distinguished early psychologists were interested in questions of how groups think, how they form common mental products, or of what nature the shared thoughts are. Durkheim (1898) labeled collectively shared cognitive products *collective representations,* which consist of the totality of beliefs and sentiments common to average members of the same society. LeBon (1895/1968) focused on the *collective mind* of a crowd, which guides contagious and common behaviors. McDougall (1920), who is considered to be one of the first professed social psychologists, introduced the con-

troversial concept of *group mind,* referring to the continuity of shared thoughts, sentiments, and tradition despite the turnover of group members. Within the realm of early psychology should be noted also the work of Lev Vygotsky, the renowned Russian social developmental psychologist. Vygotsky argued that thinking and reasoning are always products of social activity molded by society. This social activity allows the transmission of common symbolic tools that are internalized through the mediation of language and used in joint action (Vygotsky, 1962).

After the first wave of psychologists who were preoccupied with collective mental products, the interest in this topic somewhat faded away until it reappeared in the work of the three founding fathers of modern social psychology: Muzafer Sherif, Kurt Lewin, and Solomon Asch. All three were interested in group behavior and recognized that group membership affects individuals' perception of their world. Sherif (1936) demonstrated in a series of experiments how individuals in a group form a joint norm (i.e., shared belief) and how it becomes part of their repertoire that affects their perception and judgment. Lewin (1948) focused on the study of psychological forces that influence the group at any given moment and assumed that any prediction of group behavior must take into account group goals, group standards, group values, and the way a group sees its own situation and that of other groups. Asch (1946), in turn, spoke about group members' *mutually shared field,* which enables them to understand the viewpoints of others and form shared actions, feelings, or ideas.

The work of Moscovici (1988) on social representation is the most extensive elaboration of shared beliefs in the recent work of social psychology. On the basis of Durkheim's conception of collective representation, he focused on the plurality and diversity of representations within a group or society and their continuous evolution through communication.

Recently, a new interest in shared beliefs has emerged from several different directions. This new line of research does not necessarily use the term shared beliefs, but in social cognitive tradition presents the term *shared cognition* (e.g., Hardin & Higgins, 1996; Resnick, Levine, & Teasley, 1991). The work by Bar-Tal (1990, 2000) and by Fraser and Gaskell (1990) analyzes shared beliefs in groups and societies that play important functions in the formation and maintenance of social identities and in guiding social behaviors. Bar-Tal (1990) introduced the concept of group beliefs, which denotes convictions that group members are aware of sharing and consider them as defining their groupness. In this conception, group beliefs play important roles in such group processes as schism, mergence, subgrouping, and disintegration. Another direction of investigating shared beliefs emerged in the study of small groups, with the assumption that they play a determinative role in group formation and functioning (e.g., Hinsz, Tindale, & Vollrath, 1997; Klimoski & Mohammed, 1994; Nye & Brower, 1996; Tindale, Meisenhelder, Dykema-Engblade, & Hogg, 2001). According to this line of study, group members can act interdependently only when they form an understanding of goals, norms, and procedures. The development for such understanding is a condition for the successful and efficient performance of small groups.

In all groups and societies, however, shared beliefs have significant social, political, and cultural functions. First of all, shared beliefs have an important influence on group behavior. Coordinated behaviors of group members always have an epistemic basis. In the majority of cases, group members, in addition to common understanding, need rationale and justification for their social behaviors in order to take part in coordinated activities. In this role, shared beliefs in a group are often used as a rationale for social behaviors because group members share them and consider them often as truthful.

The acquired shared beliefs play a further role in the formation of new shared knowledge because there is continuous reciprocal interaction between the shared beliefs and new experiences of the society. On the one hand, the new experiences serve as a source for the formation for new shared beliefs of a group, and on the other hand, the already-accumulated shared beliefs serve as a prism through which the new experiences are understood and new beliefs are formed. Shared beliefs in a group allow a firm construction of group reality in spite of the fact that their contents often concern ambiguous social events, abstract concepts, and information that in most cases is not observed firsthand or experienced. The study of shared beliefs in groups thus opens new avenues for understanding the world of groups as well as of individuals.

SHYNESS

Definition and Categories

Shyness is a universal human emotion, sometimes viewed as a blend of fear and interest. As a personality trait, shyness is defined as excessive self-consciousness characterized by negative self-evaluation, discomfort, and/or inhibition in social situations that interferes with pursuing interpersonal or professional goals. Shyness can occur at any or all of the following levels: cognitive (e.g., excessive negative self-evaluation), affective (e.g., heightened feelings of anxiety or embarrassment), physiological (e.g., racing heart), and behavioral (e.g., failure to respond appropriately). Shyness may be triggered by a variety of situational cues. Among the most typical situations are interactions with authorities, strangers, members of the opposite sex, and unstructured social settings. Although similar in expression, introverts, like extraverts, do not fear social situations but simply prefer solitary activities. Shy individuals prefer to be with others but are restrained by evaluation concern.

Prevalence and Diagnosis

The percentage of adults in the United States reporting that they are shy has escalated from 40% (± 3%) since the 1970s up to 50% in the 1990s and 60% in recent samples. Another 40% indicated they were shy previously but no longer; 15% were situationally shy; and only 5% believed that they were never shy. Most clinical referrals for shyness meet criteria for generalized social phobia (i.e., extreme discomfort and avoidance), and many meet criteria for avoidant personality disorder (i.e., longstanding rejection sensitivity and a belief in one's social inadequacy). Other comorbid diagnoses are dysthymia, generalized anxiety disorder, specific phobias, dependent personality disorder, schizoid personality disorder, and, in a small percentage, obsessive-compulsive and paranoid personality.

Consequences

Shy individuals take less advantage of social situations, date less, are less expressive, and experience more loneliness than do nonshy people. Shy men have been found to marry and have children later, have less stable marriages, delay establishing careers, and exhibit lower levels of career achievement than their nonshy peers. A perceived inability to socialize, along with a pessimistic outlook for social interactions, may become an excuse for anticipated failure and a self-handicapping strategy (e.g., "I can't do it because I am shy"). Finally, severe shyness continuing into later life can result in social isolation, loneliness, and even chronic illness and a shorter life span.

Genetics and the Interactionist Interpretation of Shyness

Research suggesting a genetic contribution to behavioral inhibition proposes that 15% to 20% of newborns exhibit an inhibited temperament characterized by high reactivity (e.g., excessive crying and vigorous movement of head and limbs) to novel stimulation. Such infants tend to exhibit more timid behavior (e.g., playing near the primary caretaker) and have relatives who report more childhood shyness. An interactionist interpretation of trait shyness suggests that these tendencies may interact with environmental variables such as being teased or bullied, dominating older siblings, family conflict, and overprotective parenting, leading to excessive concern about social evaluation and painful self-consciousness. Finally, the development of shyness in adolescence is usually due to experiences of rejection and self-blame for perceived failure in social domains.

Neurological Bases

The neurological foundation of shyness is centered in the amygdala and hippocampus. The amygdala appears to be implicated in the association of specific stimuli with fear. The more general pervasive conditioning of background factors related to the conditioning stimuli is known as contextual conditioning. This diffuse contextual conditioning occurs more slowly and lasts longer than traditional classical conditioning. It is experienced as general apprehension

in situations that become associated with fear cues, such as classrooms and parties. Contextual conditioning involves the hippocampus, crucial in learning and memory, as well as the amygdala. The bed nucleus of the striate terminalis (BNST) is also involved and extends to the hypothalamus and the brain stem. The hypothalamus triggers the sympathetic nervous system and associated physiological symptoms, among them, trembling, increased heart rate, muscle tension, and blushing.

Culture

Cross-cultural research confirms the universality of shyness. A large proportion of participants in all cultures reported experiencing shyness—from a low of 31% in Israel to a high of 57% in Japan and 55% in Taiwan. In Mexico, Germany, India, and Canada, shyness was closer to the 40% reported in the United States. Explanations of cultural differences in shyness have focused on the distinction between collectivist cultures, which promote interdependence, thus fostering concerns about giving offense, and individualistic cultures, which promote independence, fostering self-presentational concerns. How cultures assign credit for successful actions and blame for failures also contributes to the experience of shyness if credit is externalized and blame internalized.

Treatment

Treatment includes an initial assessment (e.g., structured clinical interview, shyness inventory, fear of negative evaluation scale, depression inventory) and exposure to a hierarchy of feared situations, usually simulated in treatment sessions and in vivo, cognitive retraining, and social skills training. A treatment program that includes these elements is the 26-week Social Fitness Training (SFT) at the Shyness Clinic near Stanford University. Features of SFT, which contribute to its ecological validity, are in-group simulated exposures of feared situations, using group members and outside confederates, between-session in vivo exposures (e.g., making conversation) called behavioral homework, and the skills tool kit (like tennis drills or calisthenics) for adaptive social behavior. The kit includes emotion regulation, developing trust and intimacy, assertiveness, negotiation, empathy, and converting maladaptive thoughts, including attributions and negative relational schemas, to more adaptive cognitive patterns. As exemplified by SFT, treatment programs must consider the cognitive, behavioral, physiological, and emotional components that constitute each individual's experience of shyness.

SICKLE CELL DISEASE

Clinical Features

Sickle cell disease (SCD) refers to a group of genetic disorders that affect approximately 1 of every 400 African American newborns. The disease results from the inheritance of two abnormal alleles responsible for hemoglobin formation, at least one of these alleles being the sickle cell allele (HbS). In SCD, vascular occlusion occurs when sickled red blood cells block small blood vessels. This can cause both acute and chronic complications, including acute chest syndrome, aseptic necrosis of hips or shoulders, retinopathy, leg ulcers, cerebral vascular accidents, and chronic anemia.

Repeated episodes of severe pain, often referred to as painful crises, are the most common and disabling complication of SCD. Painful episodes are usually recurrent and unpredictable. Pain may be located in almost any area of the body, commonly the extremities, joints, low back, and abdomen. The frequency and severity of pain are highly variable, from long periods of almost no pain to painful episodes several times per month. Medical management attempts to minimize intravascular sickling and then reduce pain. This is often done with aggressive narcotic medications given orally for mild pain or intravenously for severe pain. Frequently, hospitalizations and emergency room visits are necessary.

Until recently, most parents of children with SCD did not know their newborn had the illness until their child began experiencing medical problems. Often, the problems that occur in infants and young children with SCD are severe and can be life threatening. Without proper medical treatment, death may occur, and indeed one of the periods in life in which individuals are at greatest risk for death from this disease is in the first 5 years of life. Recently, newborn screening has become more routine, and now newborns are often identified early. Although it is still common for some individuals to die suddenly and unexpectedly before age 40, many individuals live long and productive lives.

Lifestyle Consequences

Individuals with SCD still encounter significant stressors related to their disease. In children, these include retarded growth, delayed puberty, and frequent clinic visits and hospitalizations. These stressors can affect peer relationships, self-concept, and school attendance. Given their cognitive development, young children may have difficulty understanding pain and the meaning of repeated hospitalizations. They may experience feelings of helplessness and fear of the unknown and may have difficulty expressing feelings to their parents and medical professionals. Behavioral problems, especially internalizing behavioral problems, or the more silent forms of psychological distress (e.g., anxiety and depression) may occur.

As children enter adolescence and young adulthood, their disease may interfere with social relationships, academic performance, and occupational and family planning. Fears related to their illness may interfere with individualization, maturation, and separation.

Adults face decisions regarding selecting a partner and having children, issues that are often complicated by the fact that SCD is hereditary. Many adults may have problems meeting job and family responsibilities. Disability and unemployment are common, and thus so are financial problems. As adults age, they may encounter more complications related to their illness and more frequent episodes of pain. As adults approach the average life span of someone with SCD, anxiety, depression, or even preoccupation with death may occur.

The emotional reactions that can occur in individuals with SCD are often complicated by inadequate recognition and treatment of pain by health care professionals. Many physicians and nurses have not had sufficient hands-on experience treating SCD pain, and thus they may be uncomfortable with aggressive medication management. Sometimes frequent hospitalization and emergency room visits are misinterpreted as drug-seeking behavior or faking pain. Although drug-related problems may occur in individuals with SCD, excessive concern over drug addiction by health care providers can lead to undermedication and inadequate pain management. Some individuals who have frequent frustrating encounters with inexperienced health care professionals become discouraged and alienated from the health care system.

Coping with Pain and Stress Related to Illness

Individuals with SCD cope well, are often able to work, remain active in social and recreational activities, and are well adjusted psychologically. Many others, however, cope poorly, lead more limited lives, and become depressed and overly reliant on health care services for their pain management. Although some of the variability in adjustment is a result of disease severity, psychological factors, including coping strategies and social support, are significantly related to psychosocial and functional adjustment across the life span.

In adults, several factors have been related to good adjustment to SCD. Adults who have lower levels of daily stress, higher efficacy expectations, and high levels of family support have better psychological adjustment. Adults who take an active approach to coping with pain by using multiple cognitive and behavioral strategies such as diverting attention and calming self-statements are more active in household, work, and social activities. Other psychosocial factors have been associated with poorer adjustment to SCD. Adults from conflicted families and adults who use palliative coping methods for dealing with stress have poorer psychological adjustment. Overall poor psychosocial and functional adjustment also occurs in individuals who deal with pain by catastrophizing, engaging in fear and anger self-statements, and using passive strategies such as resting while neglecting to use other strategies when an episode of pain occurs. This pattern of pain coping has been associated with more severe pain; greater reductions in household, social, and occupational activities during painful episodes; and more frequent hospitalizations and emergency room visits.

In children and adolescents, there are similar relationships among these dimensions of coping, family support, and adjustment. It is interesting that factors in the parents such as maternal adjustment and the pain-coping strategies that parents use are also related to the child's adjustment. Furthermore, coping strategies in parents and their children are related, possibly because children learn to cope with their own pain by observing their parent's reactions to pain.

There is a growing recognition for the need to treat individuals with this disease from a multidisciplinary perspective. There are now comprehensive SCD centers that emphasize the importance of integrating psychosocial and educational programs with clinical and basic science research. The goals of these centers often include providing multiple types of psychological treatments such as biofeedback and individual and family therapy along with traditional medical management approaches to enhance pain management and overall coping in patients and their families.

SIMULTANEOUS CONDITIONING

Dual-task methodology involves assessing performance when individuals perform two tasks simultaneously, and in cognitive neuroscience the dual-task approach is a means to test hypotheses about shared brain substrates of behav-

ioral processes. Simultaneous conditioning uses the dual-task design and is part of a long tradition of psychological research (see Pashler, 1994, for a review). A general model for use in localization of behavioral functions is called the *functional cerebral space model* (Kinsbourne & Hicks, 1978). In this model, performance of an ongoing behavior is predicted to activate regions in the brain that are the substrates for that behavior. In a dual-task paradigm in which two behaviors are performed simultaneously, a second region of activation associated with the second task also occurs. The closer in the brain the regions activated by the two tasks are to each other, the greater the chance that there will be interference between them due to overflow of activation from one to the other.

Using the functional cerebral space approach, experiments are designed to compare simultaneous task performance under two conditions: (1) conditions in which the tasks are hypothesized to involve a common neural system and (2) conditions in which the tasks are hypothesized to involve separable neural systems. Interference should be obtained when the tasks share a common neural substrate, but there should not be interference when the tasks use separate neural systems. Eye-blink classical conditioning is a form of associative learning for which the essential brain circuitry has been almost entirely identified (Thompson, 1986). Simultaneous conditioning or the application of the dual-task approach using eye-blink classical conditioning and other behaviors is a way to test hypotheses about shared brain substrates with classical conditioning.

In the delay eye-blink classical conditioning procedure, the conditioned stimulus (CS), a tone, is presented first and followed after a delay (in most studies with humans the delay is about half a second) by a corneal air puff unconditioned stimulus (US), and the CS and US end together. Early in the conditioning process, when the first paired CS-US presentations are made, participants respond by producing a reflexive eye-blink unconditioned response (UR) to the US. After an average of 40 paired presentations of the CS and US, young adult participants produce conditioned responses (CRs) by blinking before the onset of the US. The well-learned response or CR is an eye blink to the tone occurring just before the onset of the air puff US. Although the response is timed precisely, the participant typically has little awareness of blinking to the tone CS. This absence of awareness that learning is occurring coupled with the fact that medial temporal-lobe circuits are not essential for acquisition qualifies delay eye-blink conditioning as a nondeclarative form of learning.

The neural circuitry for this form of learning has been documented in nonhuman mammals using a variety of techniques (see Steinmetz, 1996; Thompson & Krupa, 1994, for reviews) and extended to humans in studies of neurological patients (Woodruff-Pak, 1997) and in brain imaging studies in normal human adults (e.g., Logan & Grafton, 1995). The neural pathways for eye-blink classical conditioning involve sensory pathways for the CS and US that converge in the cerebellum on the same side (ipsilateral) as the eye that receives the air puff. The association between the tone CS and airpuff US occurs at two loci within the cerebellum: the interpositus nucleus in nonhuman mammals (globose nucleus in humans) and cerebellar cortex. Using this clear delineation of the eye-blink classical conditioning circuitry, we can undertake behavioral dual-task studies to examine whether tasks interfere with one another and draw implications about the locus of activation of these tasks.

Papka, Ivry, and Woodruff-Pak (1995) conducted a dual-task study to test the hypothesis that timed-interval tapping and eye-blink classical conditioning are both dependent upon cerebellar cortical substrates. Eye-blink conditioning was assessed with a 400-ms delay paradigm, and concurrent with conditioning, separate groups of subjects were tested on a timed-interval tapping task, an explicit memory recognition task, a choice reaction-time task, or, for a baseline control, video watching. The hypothesis was that simultaneous conditioning and timed-interval tapping performance would produce interference, whereas simultaneous conditioning and memory recognition, choice reaction time, or video watching would not produce interference. This hypothesis was supported, and Papka et al. reported selective interference between eye-blink conditioning and timed-interval tapping but not during any of the other simultaneous conditioning situations.

A task developed to test motor learning is rotary pursuit, in which the participant holds a stylus on a rotating circular disk. With practice, the time that the participant is able to keep the stylus on target increases, and errors of going off the target decrease. Simultaneous conditioning with rotary pursuit produced little or no interference, suggesting separate neural substrates for the two tasks (Green & Woodruff-Pak, 1997). Word-stem completion priming is a form of learning in which previous experience with a word makes it more likely to be cued by a word stem. Additional work in our laboratory indicated that simultaneous conditioning with word-stem completion priming produced no interference with either task, supporting the contention that these two forms of learning have separate neural substrates (Green, Small, Downey-Lamb, & Woodruff-Pak, in press).

A stronger test of the separability of these two nondeclarative forms of learning and memory was carried out in my laboratory by testing young and older adults on simultaneous conditioning and word-stem completion. The fact that older adults tend to perform more poorly as the complexity of the task is increased is interpreted as an indicator of limited processing resources. The perspective of a diminution of processing capacity in older adulthood is longstanding (e.g., Birren, 1964; Welford, 1958), and contemporary research addressing issues such as aging and working memory continue to reinforce this position. From

the perspective that older adults have a diminished processing capacity, it follows that older adults might be impaired in simultaneous conditioning and word-stem completion priming even though younger adults are not impaired in this dual-task situation. Comparing groups of younger and older adults on simultaneous conditioning and priming and comparing their performance to conditioning and priming as single tasks, Downey-Lamb (1999) found no evidence of interference in the simultaneous condition for the young or older adults. Thus, simultaneous conditioning studies demonstrate tasks that do not share the same neural substrate as well as tasks that share cerebellar substrates.

SINGLE PARENTHOOD

Single parenthood results when a parent divorces (57%), a child's parents are not married (33%), or a parent becomes widowed (6%; Rawlings & Saluter, 1995). The number of single-parent families in the United States increased from 9% of the general population in 1960 to 28% in 1990 and is expected to increase in relation to two-parent families into the twenty-first century (Rawlings & Saluter, 1995).

Finer (1974) set forth a comprehensive international report on single-parent families. The report noted that single-parent families were faced with problems such as social isolation and loneliness, financial hardships, and pressures on children to be responsible for domestic duties that are beyond their capabilities.

Research on single parenthood has tended to focus on the impact on children and the impact on parents.

Impact on Children

Although some children from single-parent families do quite well psychologically, overall there is an increased risk for psychological and behavioral problems. A review of the literature by Hilton, Desrochers, and Devall (2001) shows that single-parent children, as compared to intact families, tend to have lower levels of psychological well-being (Amato & Keith, 1991); internalizing problems such as anxiety, depression, withdrawal, and inhibition (Holden, 1997); externalizing problems such as noncompliance, acting out, and aggression (Holden, 1997); school performance deficits (Acock & Demo, 1994); and health problems (Dawson, 1991). Hetherington, Cox, and Cox (1978) also found that many of these problems surface during the first year following divorce (e.g., children tend to be more aggressive, oppositional, distractible, and demanding).

Crossman and Adams (1980) described two social-psychological theories that can be used to understand the potential negative effects of divorce on children. Crises theory suggests that divorce is an undesirable and stressful event that can have adverse consequences for a family member. According to crisis theory, children who are the most sensitive to the stressors associated with divorce tend to experience the most problems.

Zajonc (1976) provides a second theoretical perspective that suggests that divorce can undermine the amount of time that the parent and child spend interacting, thereby creating negative consequences. According to Zajonc's theory,

single parents tend to have less time to spend with their children because of additional role demands. The children's social and cognitive development thus tends to suffer because they do not have enough time to interact with their parents.

Impact on Parent

The most common initial reaction to single parenthood is depression. Often the parent feels victimized, alone, and angry. He or she tends to worry about unpredictable income and poor housing and to feel inadequate (Miller, 1980). Other emotional reactions experienced by single parents include guilt or a sense of failure about a marriage breakdown, grief, fear, anxiety, confusion, and, in some cases, relief (Burgess & Nystul, 1977). The advent of single parenthood may also result in increased strain on the single parent's time, energy, emotions, and ability to work (Burgess & Nystul, 1977).

There has been a limited amount of research on the factors associated with successful single-parent families. Barry (1979) identified tasks for the adjustment period and tasks for the new family period that promote a positive single-parenthood experience.

Tasks for the Adjustment Period

1. Family members must recognize that changes have occurred within the family and that they will affect each member.
2. It must be realized that it will take time for each family member to experience the full impact of these changes.
3. Each family member needs to be allowed to mourn the loss of the parent who has left the family.
4. The limits and opportunities of the new situation must be assessed realistically.
5. The parent should try to understand, and to be accepting and supportive of, the children's attempts to react and adjust to the situation.
6. Parents should seek professional help for themselves and their children if progress on these tasks is not occurring.

Tasks for the New Family Period

1. The role of the parent who has left the family must be clarified in a manner that maximizes meaningful ongoing involvement by the noncustodial parent.
2. Problem-solving and decision-making skills should be applied to the full range of familial concerns such as sibling relationships and financial planning.
3. Communication and leadership skills should be used to readjust family roles for parents and children.
4. Realistic goals (short- and long-term) should be established for each family member and addressed in an ongoing, meaningful manner.
5. Social networks should be established that support the personal goals that are set.
6. Positive parenting principles should be practiced.

Recent Research Trends

To a large degree, research on single parenthood has focused on single mothers and been generalized to all parents (Hilton et al., 2001). More recently, researchers have analyzed the single-parenthood experience in terms of single mothers, single fathers, and intact families. Hilton and Devall (1998) noted that divorce tends to have a positive effect on the parenting of fathers (when they become single parents) and a negative effect on mothers (when they become single parents). Single fathers were also rated to be as effective (in terms of positive parenting) as single and married mothers and rated more positive (in terms of parenting) than married fathers (Hilton et al., 2001; Hilton & Devall, 1998). Collectively, the research relating to single fathers appears to have significant implications for custody decisions.

Financial strain has been identified as an important factor in undermining a woman's ability to adjust to the role in single parenthood. In this regard, Hilton et al. (2001) noted that single mothers have 47% the annual income of intact families, whereas single fathers have 86% of the annual income of intact families.

Coley (1998) evaluated the effects of father figures on children's socialization experiences. She found that divorced fathers had a more positive effect on children's achievement than did never-married father figures. Culture and gender were also important in terms of promoting socialization. African American children (vs. Anglos) and females (vs. males) benefited more from a father figure.

SINGLE-PARTICIPANT RESEARCH DESIGNS

Single-participant research designs involve the intensive study of one organism continuously or repeatedly across time. The organism may be a person or a single molar unit such as an industrial organization or a political unit. As with conventional group designs based on reasonably large samples of participants, single-participant designs are employed to determine whether different variables are related or whether a treatment or intervention causes some effect on relevant response measures. There are situations in which it is more meaningful, more convenient, more ethical, and less expensive to study one or very few participants intensively than to study many participants. A basic difference between group and single-participant designs is that one or very few observations are generally obtained from each participant in group designs, whereas many observations are obtained from one (or very few) participant across time in the case of single-participant designs. The design categories of (1) correlational, (2) quasi-experimental, and (3) experimental that frequently are used to classify different types of group designs also can be used to classify various single-participant designs.

Correlational Designs

Single-participant correlational designs involve a collection of scores obtained across time (a time series) on some dependent variable of interest and, in addition, either (1) a series of scores on some other variable collected at the same time points (the concomitant series) or (2) a log of events that occur during the time series. An analysis is then carried out to determine whether changes on the dependent-variable time series are associated with changes in the concomitant series or the occurrence of events that have been recorded.

Quasi-Experimental Design

The quasi-experimental AB design consists of two phases: the baseline or A phase and the intervention or B phase. Data are collected during the A phase to describe the behavior before the treatment is introduced. After the baseline data are collected, the experimenter introduces an intervention, and data continue to be collected during the B phase. A major weakness of the AB design is that it is often difficult to know if some condition other than the intervention has changed between the A and B phases. Stronger designs are required to cope with this problem.

Experimental Designs

Three single-participant experimental designs are described here; others exist but are slight variants of these basic designs. Each of these designs provides greater certainty that a planned intervention is responsible for a change observed in time-series data than is provided by the AB quasi-experiment.

Reversal Designs

The direct extensions of the AB design are the ABA (baseline-intervention-baseline) and ABAB (baseline-intervention-baseline-intervention) designs. The ABAB design is often referred to as a reversal design in the behavior modification literature because the intervention condition is said to be reversed (more appropriately, withdrawn) after it is first applied. The advantage of these designs is that there is repeated demonstration of the effect of changing conditions that are manipulated by the experimenter. There are many situations, however, in which it is illogical to expect the behavior to revert to a preintervention level or impractical (or unethical) to reintroduce early conditions. Other single-participant designs can solve these problems.

Multiple Baseline Designs

Most of the difficulties associated with reversal designs can be solved with some version of the multiple baseline design. In a sense, this design is a collection of AB designs. Data are collected on two or more baseline series, and an intervention is applied to each one. Because the intervention is introduced in a staggered manner to the various baselines, it is implausible that some event unrelated to the intervention is the cause of the apparent effect on each series.

Single-Participant Randomized Experiments

Unlike the previously described designs, the single-participant randomized experiment does not employ a different condition throughout each of a small number of phases. Instead, the order of administration of two (or more) different conditions is randomized. A disadvantage of this approach is that the logic of the design dictates the use of treatments having very rapid effects that will not carry over long enough to contaminate the other treatments.

Comparison of Single-Participant and Group Designs

Single-participant and group designs differ in terms of several important characteristics, including data collection problems, the question answered, and data analysis. Many variables (both independent and dependent) are not easily (or at reasonable cost) employed repeatedly. This aspect of single-participant designs is perhaps the most limiting.

At a general level, both single-participant and group experimental designs provide an answer to the question of whether there is a treatment effect. They differ in terms of how the effect is defined and studied. The ABAB design, for example, provides important information on the form of change across time (both within and between phases) for a single participant, whereas the between-groups design provides an estimate of the intervention magnitude (generally at one time point) for a specified population of participants. The usefulness of the information obtained from each design depends on the type of external validity of greatest relevance.

Visual analysis (rather than statistical inference) is the norm for single-participant designs; however, a trend is developing among some researchers to employ formal statistical methods regardless of design.

SIXTEEN PERSONALITY FACTOR QUESTIONNAIRE

The Sixteen Personality Factor Questionnaire (16PF) is one of the most widely used, theory-based instruments for assessing normal-range personality characteristics in adults. The test has been translated into nearly 50 languages and is used to evaluate a set of 16 reasonably independent characteristics that predict a wide range of socially significant criteria. Adaptations of the original questionnaire have been developed for assessing personality in younger populations, effectively extending the age range of the test to 6 years old.

Raymond B. Cattell and a series of coauthors developed the test over a period of many decades following extensive research intended to clarify the basic organization of human personality. Cattell was interested primarily in identifying a relatively small set of *source traits* that could be used to explain variations in the much larger set of surface characteristics observable in behavior and recorded in language. Cattell began his search with the English lexicon because he was convinced that “all aspects of human personality which are or have been of importance, interest, or utility have already become recorded in the substance of language” (Cattell, 1943, p. 478). Whether it is true that language exhaustively delimits personality, it is certainly true that language extensively describes personality. About the time Cattell began his studies, Allport and Odbert (1936) had identified about 18,000 words in the unabridged English dictionary that described aspects of human behavior. When Cattell eliminated terms that were essentially evaluative (e.g., adorable, evil) or metaphorical (e.g., alive, prolific) or that described temporary states (e.g., rejoicing, frantic), 4,504 terms remained. Cattell began with that list and conducted a series of analyses to eliminate overlap among them. His analyses encompassed a variety of perspectives (e.g., peer ratings, self-reports), populations (e.g., undergraduates, military personnel, working adults), and methodologies (e.g., cluster analysis, factor analysis). By beginning his search with the entire universe of trait names and conducting the reduction systematically, Cattell reasoned that the set finally remaining must be judged to be source traits. In the same way that water, for example, could be conceptualized as a weighted combination of elementary molecules (two parts hydrogen, one part oxygen), Cattell believed that human characteristics such as adaptability or competitiveness could be conceptualized as weighted combinations of this small set of source traits.

The first publication of the 16PF did not occur until 1949, more than a decade after Cattell began his studies. Since then the test has undergone five major and several minor revisions. The most recent, in 1993, was the last Cattell completed before his death in 1998.

The current test contains 185 items, requires 35–50 minutes to complete, and has a 5th-grade reading level. The test can be scored by hand, but computerized scoring and

an extensive array of interpretive reports are also available. Many of the items in the test are statements (e.g., "I get embarrassed if I suddenly become the center of attention in a social group") to which the examinee responds by choosing from three options (true, uncertain, false). Others present a set of contrasted choices (e.g., "If I could, I would rather exercise by (a) fencing or dancing, (b) uncertain, (c) wrestling or baseball"). The test provides scores for 16 primary scales and five global factors. The global factors result from factor analyses of the 16 primary scales and are conceptualized as major organizing influences behind the primary scales. The average test-retest scale reliability coefficient for the primary scales is .83 after a few weeks and .72 over a period of two months. Corresponding values for the global scales are slightly higher. Internal consistency reliabilities of the primary scales average .75.

The primary scales of the test, which are designated by alphanumeric symbols, are as follows: A—Warmth, B—Reasoning, C—Emotional Stability, E—Dominance, F—Liveliness, G—Rule-Consciousness, H—Social Boldness, I—Sensitivity, L—Vigilance, M—Abstractedness, N—Privateness, O—Apprehension, Q_1—Openness to Change, Q_2—Self-Reliance, Q_3—Perfectionism, and Q_4—Tension. The five global factors (Extroversion, Anxiety, Tough-Mindedness, Independence, and Self-control) assess features similar to those described as the Big Five in personality research. The 16PF can also be scored for approximately 100 scales that derive from years of empirical research on 16PF applications in clinical, counseling, and organizational psychology. The 16PF provides three response style indicators: Impression Management, Infrequency, and Acquiescence. These scales help identify unusual response patterns that may affect the validity of the profile.

The extensive body of research findings that have accumulated over time enhances interpretation of the 16PF. A great deal is known, for example, about how test scores relate to career preference, job performance, academic achievement, creativity, interpersonal relationships, and marital satisfaction. Clinical research with the test suggests that it can be useful in understanding the dynamics of adjustment and personality disorders, addiction, and spousal abuse.

The 16PF is used primarily to provide an objective determination of what a person is like and, therefore, to tell what the person is likely to do in various situations. For example, will the person function effectively in jobs that require a strong technical orientation? Can she be counted on to finish things she starts? Will he be an effective leader? Are these the kinds of people who are likely to handle high-stress situations well?

The 16PF's content overlaps with that of other omnibus instruments designed to assess normal-range personality, such as the California Psychological Inventory, the NEO Personality Inventory, and the Personality Research Form. However, the multivariate model that underlies the 16PF is distinct from those on which these other instruments are built, and the 16PF is embedded within a broader theoretical framework that Cattell developed to address individual differences in learning and human development (Cattell, 1979, 1980).

Since 1949, the 16PF has developed into a widely used instrument for assessing adult personality. A long history of empirical research and an origin within a well-established theory provide a rich source of interpretation for test users.

SLEEP CYCLE

In mammals including humans and in birds, sleep has a cyclic structure. Sleep electroencephalogram (EEG) recordings reveal the alternating occurrence of periods of non–rapid eye movement (nonREM) and rapid eye movement (REM) sleep. One sleep cycle consists of one nonREM and one REM period. Normal adult humans have 3 to 6 sleep cycles per night (see Figure 1).

The major portion of slow wave sleep (SWS) is found during the first nonREM period. In all sleep cycles the duration of the nonREM period is longer than that of the REM period. However, the nonREM-REM ratio changes across the sleep cycles with an increasing duration of REM periods throughout the night. Similarly REM density (the amount of REMs during REM periods) increases. The mean duration of sleep cycles in human adults is widely constant and ranges intraindividually from about 85 to 115 min. The average duration of the first sleep cycle is about 70 to 100 min; the average length of the second and the following cycles is approximately 90 to 120 min.

The duration of the sleep cycle in a certain species is correlated to the ratio of the body volume and body surface. Therefore, in mice it is about 7 min, and in elephants 180 min.

Sleep is affected by age, illness, and drug use. The cyclic structure of sleep exists already in the newborn, though

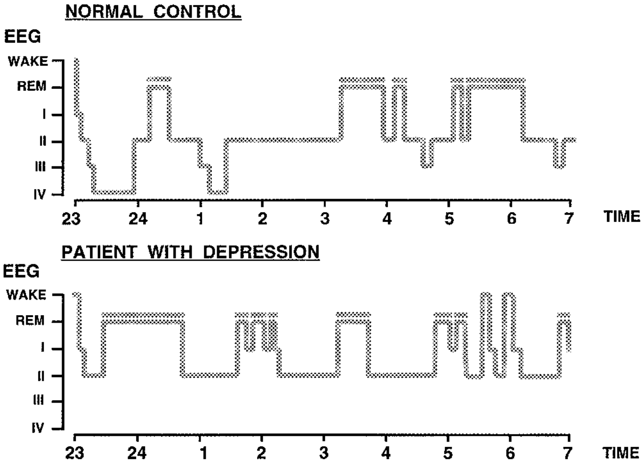

Figure 1. Hypnograms of a young normal control patient and an elderly patient with depression (REM, rapid eye-movement sleep; I–IV, stages of nonREM sleep).

with a shorter period (about 50–60 min) than in adults. Newborns and infants spend most of the time asleep. They sleep polyphasically and have the highest amount of REM sleep (about 50% of sleep). The amount of REM sleep decreases during childhood and adolescence, and then remains widely stable for several decades. During senescence it may decrease. SWS, however, shows a sharp decrease during adolescence followed by a further decline. In women menopause is a major turning point in the decrease of SWS, whereas in men a continuous decrease occurs.

During depression, changes in sleep are similar to those found in aging. These include a disturbed sleep continuity, decrease of SWS and disinhibition of REM sleep (shortened REM latency [the interval between sleep onset and first REM period], prolonged first REM period, and enhanced REM density; see Figure 1). Differences between patients with depression and age-matched controls may be restricted to the first sleep cycle with a shorter REM latency and a decreased amount of SWS in the patients (Lauer et al., 1992). Due to synergism of depression and aging, elderly depressed patients show the most distinct sleep-EEG changes. Sleep onset REM periods (SOREMPs, e.g., a REM latency shorter than 10 min) may occur during depression. In healthy subjects, SOREMPs occur rarely. Patients with narcolepsy also frequently show SOREMPs. In young patients with depression, a shift of the major portion of SWS from the first to the second sleep cycle is a robust finding. Severe disruption of the sleep-wake cycle is a symptom of Alzheimer dementia and is one of the major problems of managing these patients.

Most antidepressants suppress REM sleep. REM suppression is linked to the prolongation of the REM latency. Various substances differ in their ability to suppress REM sleep. Furthermore, this effect depends on the dosage. Potent suppressors like clomipramine may abolish REM sleep totally. Cessation of antidepressants is followed by a REM rebound. However, some antidepressants are effective but do not diminish REM sleep. Trimipramine and mirtazapine even enhance REM sleep in depressed patients (Sonntag et al., 1996).

There are interactions between the sleep cycle and various other ultradian rhythms. In males, spontaneous erections (nocturnal penile tumescence, or NPT) occur in a rather strict association with REM periods. Renin is the key enzyme of the renin-angiotensin-aldosterone system regulating water and salt metabolism. Plasma renin activity (PRA) shows oscillations of about 90 min strongly linked to the nonREM-REM sleep cycles. PRA increases in nonREM sleep and decreases in REM sleep. Increases of SWA and PRA are connected (Brandenberger et al., 1994).

The sleep cycle underlies a complex regulation. REM-on and REM-off neurons of the brain stem are thought to trigger the alternations of nonREM and REM episodes. Cholinergic neurons at the junction of the pons and the midbrain begin to discharge before the onset of REM. EEG activation is promoted via cholinergic projections to the thalamus, and projections to the reticular formation enhance excitability and discharge activity in these effector regions for REM phenomena. In turn, these mesopontine cholinergic neurons are modulated by the REM-suppressing norepinephrinergic locus coeruleus and serotonergic dorsal raphe projections (McCarley, Greene, Rainnie, & Portas, 1995). Furthermore, various neuropeptides participate in sleep regulation. A reciprocal interaction of growth hormone-releasing hormone (GHRH) and corticotropin-releasing hormone (CRH) influences the amount of SWS and nocturnal hormone secretion. GHRH promotes SWS and GH and inhibits cortisol, whereas CRH prompts the opposite effects. Changes of the GHRH-CRH ratio probably contribute to changes of sleep during aging (decline of GHRH activity) and depression (CRH overactivity; Steiger & Holsboer, 1997). Administration of vasoactive intestinal polypeptide, which is found in marked concentrations in the suprachiasmatic nucleus, decelerated the nonREM-REM cycle in young men and advanced the occurrence of the cortisol rise.

SLEEP DISORDERS

The field of sleep medicine has grown to comprise a broad spectrum of syndromes, disorders, and diseases. The predominance of psychology and psychiatry in the field has given way to increasing neurology and pulmonary medicine involvement, and most centers prefer a multidisciplinary approach. Comprehensive sleep disorders centers, accredited by the American Academy of Sleep Medicine (AASM), provide clinical assessment, polysomnography, and treatment for patients. The AASM has developed a diagnostic and classification manual for sleep disorders, as well as evidence-based standards of practice.

Sleep-related breathing disorders are the most common diagnoses made in sleep centers. Based on a random sample of 602 employed people between 30 and 60 years of age, Young et al. (1993) estimated that 4% of men and 2% of women meet diagnostic criteria for sleep apnea syndrome. Obesity, large neck circumference, and hypertension are associated with sleep apnea. Most patients are loud snorers and are sleepy during the day, although these complaints often come from family members rather than the patients themselves.

The polysomnogram provides objective evidence of sleep apnea. Airflow, chest and abdominal movement, and oxygen saturation are monitored continuously during the night. Sleep stages are identified by recording the electroencephalogram, eye movements, and chin muscle tone. Initially, breathing was assessed by counting the number of episodes of complete cessation of airflow lasting more than 10 seconds. More recently, decreases of airflow and arousals related to diminished breathing have been recognized as being clinically significant as well. Treatment decisions are based on an apnea-hypopnea index that combines all sleep-related breathing events, as well as oxygen saturation, cardiac arrhythmia, and daytime symptoms.

The cause of sleep apnea appears to be susceptibility of the upper airway to collapse during inspiration when muscle tone decreases with sleep onset. The most common treatment for sleep-related breathing disorders is continuous positive airway pressure (CPAP) delivered by a mask over the nose. Patients are titrated during polysomnography for the minimum pressure that resolves apnea, eliminates snoring, and improves the sleep pattern. Regular use of CPAP usually improves daytime sleepiness and blood pressure control. Treatment alternatives have been developed for patients unable to tolerate CPAP, including upper airway surgery and oral appliances.

Restless legs syndrome and periodic limb movement disorder are associated with prolonged latency to sleep onset and daytime sleepiness. Patients complain of crawling sensations or involuntary jerking of the legs, particularly during the evening or when sitting for prolonged periods. During polysomnograms, sensors detect muscle contractions or overt movements of the legs recurring at regular intervals of about 30 seconds. The movements may cause brief bursts of waking electroencephalographic activity or increased heart rate. The clinical significance of these movements is debated, but with adequate treatment many patients report resolution of the restlessness, improved concentration during the day, and decreased daytime sleepiness.

Insomnia may arise from a variety of causes, and a variety of treatments is available. Sleep-onset insomnia arises from anxiety disorders or jet lag and is often perpetuated by psychophysiological conditioning. The anxiety component may respond to cognitive behavioral therapy or relaxation techniques. A stimulus-deconditioning protocol specific to patients with insomnia has been developed and demonstrated to be effective.

Sleep maintenance insomnia and early morning awakening are hallmarks of depression. Patients with depression who undergo polysomnography also have a shortened latency to rapid eye movement (REM) sleep. This biological marker of depression may appear before a clinical depression is present and may persist despite adequate treatment. Tricyclic antidepressants usually have a beneficial effect on sleep continuity and mood. REM sleep latency may also be normalized. Serotonin reuptake inhibitors also suppress REM sleep but may increase the number of awakenings during the night.

Narcolepsy typically presents at about age 18 with excessive daytime sleepiness. Classically, patients have irresistible sleep attacks as well as accessory symptoms including cataplexy (a sudden loss of muscle tone with strong emotion or surprise), sleep paralysis (an inability to move for several minutes on awakening or at sleep onset), hypnagogic hallucinations (visual, tactile, or auditory sensations, often occurring in association with sleep paralysis) and automatic behaviors. There is a strong association with an HLA antigen and probably a genetic susceptibility to narcolepsy. Recent studies have linked narcolepsy with low levels of hypocretin (orexin) in the central nervous system.

Establishing a diagnosis of narcolepsy requires a polysomnogram followed by a Multiple Sleep Latency Test (MSLT). The MSLT provides an objective measure of sleepiness, as defined by the tendency to fall asleep during the day. The presence of REM sleep during two or more of the 20-minute naps on the MSLT is considered consistent with a diagnosis of narcolepsy. Narcolepsy often responds to treatment with stimulants. Methylphenidate and pemoline have been used for many years; modafanil is a recent alternative. Due to the potential for tolerance and elevation

of blood pressure, amphetamines are usually reserved for patients who fail other therapies. Cataplexy reaches a level requiring treatment in some patients. Antidepressants, either tricyclics or serotonin reuptake inhibitors, are effective in controlling cataplexy.

Patients with parasomnias are infrequently seen at sleep disorders centers but are of theoretical interest as they may represent dissociation of aspects of sleep stages. Intrusions of waking behaviors in non-REM sleep include sleepwalking, night terrors, episodic nocturnal wandering, and nocturnal eating disorders. Although extremely common and usually benign in adolescents, parasomnias in adults may be accompanied by violence and therefore require treatment. REM behavior disorder is a failure of the normal muscle paralysis that prevents movement during REM sleep, thus representing an intrusion of wakefulness during REM sleep. Patients with this disorder act out their dreams, occasionally causing significant injuries.

With increasing diagnostic accuracy and improved treatment efficacy, public awareness of sleep disorders has increased markedly. Research efforts are underway to determine whether treatment of sleep-related breathing disorders decreases the risk of heart attack and stroke. Sleep apnea and other disorders causing daytime sleepiness contribute to automobile accidents, employee absenteeism, and mood disorders, among other significant consequences. Sleep disorders centers provide a focus for diagnosis and treatment as well as a resource for research and teaching.

SLEEPER EFFECT

A sleeper effect in persuasion is a delayed increase in the impact of a persuasive message. In other words, a sleeper effect occurs when a communication shows no immediate persuasive effects, but, after a period of time, the recipient of the communication becomes more favorable toward the position advocated by the message. As a pattern of data, the sleeper effect is the opposite of the typical finding that induced opinion change dissipates over time.

The term *sleeper effect* was first used by Hovland, Lumsdaine, and Sheffield (1949) to describe opinion change produced by the U.S. Army's *Why We Fight* films used during World War II. Specifically, Hovland et al. found that the film *The Battle of Britain* increased U.S. Army recruits' confidence in their British allies when the effect of this film was assessed nine weeks after it was shown (compared to an earlier assessment).

Hovland et al. (1949) interpreted their findings in terms of a dissociation discounting cue hypothesis. According to this hypothesis, a sleeper effect occurs when a persuasive message is presented with a discounting cue (such as a low credible source or a counterargument). Just after receiving the message, the recipient recalls both message and discounting cue, resulting in little or no opinion change. After a delay, as the association between message and discounting cue weakens, the recipient may "remember what was said without thinking about who said it" (Hovland, Janis, & Kelley, 1953, p. 259). In other words, a sleeper effect occurs because of a spontaneous dissociation of a message and a discounting cue over time.

Hovland and Weiss (1951) provided a test of the dissociation hypothesis by giving participants persuasive messages attributed to either a trustworthy or an untrustworthy source. The results showed an increase in the percentage of people agreeing with the message given by the untrustworthy source four weeks after the presentation compared to immediately after the message was received.

The Hovland and Weiss (1951) study gave the sleeper effect scientific status as a replicable phenomenon and the dissociation discounting cue hypothesis credibility as the explanation for this phenomenon. The sleeper effect was discussed in almost every social psychology textbook of the time, appeared in related literatures (e.g., marketing, communications, public opinion, and sociology), and even obtained some popular notoriety as a lay idiom.

However, in 1974 Gillig and Greenwald were unable to produce a sleeper effect. In their studies, over 600 participants received messages attributed to a low credible source. Unlike the Hovland and Weiss (1951) study, the results revealed no indication of a sleeper effect.

The Gillig and Greenwald (1974) research raises an important question: Is the sleeper effect a reliable phenomenon? Studies by Gruder et al. (1978) and by Pratkanis, Greenwald, Leippe, and Baumgardner (1988) answered "yes" to this question and have specified empirical conditions needed for producing a sleeper effect. In both the Gruder et al. and Pratkanis et al. studies, reliable sleeper effects were obtained when (1) message recipients were induced to pay attention to message content by noting the im-

portant arguments in the message, (2) the discounting cue came after the message, and (3) message recipients rated the credibility of the message source immediately after receiving the message and cue. For example, in one experiment, participants underlined the important arguments as they read a persuasive message. After reading the message, subjects received a discounting cue stating that the message was false and then rated the trustworthiness of the message source. This set of procedures resulted in a sleeper effect.

The procedures developed by Gruder et al. (1978) and by Pratkanis et al. (1988) are sufficiently different from earlier studies to warrant a new interpretation of the sleeper effect. As a replacement for the dissociation hypothesis, Pratkanis et al. proposed a differential decay interpretation. According to this hypothesis, a sleeper effect occurs when (1) the impact of the message decays more slowly than the impact of the discounting cue and (2) the information from the message and from the discounting cue is not immediately integrated to form an attitude (and thus the discounting cue is already dissociated from message content).

Although much of the research on the sleeper effect has focused on the discounting cue manipulation, researchers have developed other procedures for producing sleeper effects, including (1) delayed reaction to a fear-arousing message, (2) delayed insight into the implications of a message, (3) leveling and sharpening of a persuasive message over time, (4) dissipation of the effects of forewarning of persuasive intent, (5) group discussion of a message after a delay, (6) the dissipation of reactance induced by a message, (7) delayed internalization of the values of a message, (8) wearing-off of initial annoyance with a negative or tedious message, (9) delayed acceptance of an ego-attacking message, and (10) delayed impact of minority influence. Although these other procedures for obtaining a sleeper effect have been less well researched, they may indeed be more common in everyday life than sleeper effects based on the differential decay hypothesis.

SMALL SAMPLE STATISTICS

The notion of small sample or small-*n* statistics was first developed by Gosset, a statistician working at the Guinness Brewery in the United Kingdom. One of his duties was to analyze samples of freshly brewed stout. Due to the inherent variability in the nature of the brewing process and the length of time required to test samples, Gosset experimented with the idea of substantially reducing the number of samplings taken from the very large number of available barrels. He found that the sampling distribution for small samples differed markedly from the normal distribution. Further, the distribution changed depending on the size of the sample, giving rise to a whole family of distributions. The results of his experiments with small samples led to the development of the *t* distribution, which Gosset published in 1908 using the pseudonym Student. In addition to being the first to recognize explicitly and deal with the problem of small samples, Gosset was also the first to combine experimental design with statistical testing and probably also the first to suggest anything like the .05 level as a reasonable criterion for rejecting the null hypothesis. Although not immediately recognized as such, Gosset's work with small samples was a critical breakthrough in the history of statistics, leading to the development of a number of other procedures, including the analysis of variance.

The *t* distribution, like the normal (z) distribution, applies to the testing of the null hypothesis that two samples have been randomly selected from the same population and that the calculated statistics (mean and standard deviation) are unbiased estimates of the population parameters. However, unlike the z, the t distribution for small samples does not require prior knowledge or precise estimates of the population mean and standard deviation. Whereas both the z and t distributions are symmetrical, the t distribution becomes increasingly platykurtic as sample size decreases. Platykurtic curves are less asymptotic (i.e., heavier in the tails) compared to the normal curve. This difference leads to marked discrepancies between corresponding t and z scores, especially for small sample sizes. For example, a t of 2.57 with 5 degrees of freedom (df) is associated with a probability (p) value of .05 (two-tailed), whereas for the normal distribution a z score of only 1.96 is required for $p = .05$. A t value of 2.57 with df = 5 indicates statistical significance at the 5% level. For the normal curve, a z of 2.57 would indicate statistical significance at the 1% level.

Extension of Gosset's work on the t distribution to more than two groups was accomplished by the British statisti-

cian Fisher, perhaps the most influential statistician of the twentieth century. Fisher proposed the first theoretical formulations of the analysis of variance and the *F* distribution in a series of classic works starting around 1925. As with the *t* distribution, the *F* distribution is represented by a family of distributions. However, whereas the *t* distribution is characterized by a single df, the *F* distribution is characterized by two separate degrees of freedom, one representing between-groups variability and one within-groups variability (error).

What Constitutes a Small Sample?

Although there is no definitive answer to this question, it is conventional to set the cutoff between a small and a large sample at about 30. Though arbitrary, this judgment stems from comparing the *t* and *z* distributions and noting that discrepancies between *t* and *z* decrease as df increases and that *t* approaches *z* quite closely long before it reaches its limit at df = infinity, when $t = z$. Convergence between *t* and *z* becomes rather rapid at and beyond df = 30. For example, for df = 30, the comparative values for *t* and *z* are, respectively, 2.042 and 1.960 for $p = .05$, 2.750 and 2.576 for $p = .01$, and 3.646 and 3.291 for $p = .001$.

Other Small Sample Statistics

The *t* test and the analysis of variance *F* test procedures were explicitly designed for use with small samples, although they are valid for large samples as well. There are, however, many other statistical methods applicable to small samples, including primarily the nonparametric, or distribution-free, methods. These techniques were designed mainly for use with data that do not fit the definition of either ratio or interval levels of measurement but rather are either ordinal or nominal measures. For nonparametric statistics, no assumptions are made regarding parameters, especially relating to variance estimates. For this reason, nonparametric methods are sometimes used for ratio and interval scale measures when sample sizes are small and there is a likelihood that some of the underlying parametric assumptions are being violated. Among the procedures that have been used in such situations are Fisher's exact test, Kendall's tau, the Kruskal-Wallis *H* test, the Mann-Whitney *U* test, the median test, the sign test, Spearman's rho, and Wilcoxon's *t* test. However, it should be noted that parametric procedures have been shown to be robust to violations of many of their underlying assumptions and that use of nonparametric procedures in such cases may lead to decreased statistical power.

A relatively new approach to small-sample statistical analysis is time-series analysis (TSA). This procedure is appropriate for repeated and equally spaced observations on single units or even single subjects, making it the ultimate in small-sample statistical procedures. Because TSA involves repeated observations, serial dependency (autocorrelation) in the data is an important issue. Identification of an appropriate underlying statistical model is necessary to evaluate and remove serial dependency from the data. This is typically accomplished using one of several alternative autoregressive integrated moving average (ARIMA) models. The most widely used procedures in the social and behavioral sciences involve interrupted TSA. These techniques have wide utility in applied research because of their ability to estimate intervention (interruption) effects and to identify patterns in the data such as trend effects, cyclical (seasonal) variation, and patterns of serial dependency.

SMOKING BEHAVIOR

Epidemiology

Recent estimates indicate that approximately 60 million Americans (about 29% of the population) and one third of the world's adult population smoke cigarettes. According to the Centers for Disease Control, over 440,000 deaths per year in the United States are attributable to smoking. Worldwide, an estimated 4 million deaths can be attributed to smoking and use of other tobacco products. During the past few decades, overall rates of smoking prevalence have decreased in Western countries. However, in the 1990s, rates increased for certain groups, including women and high school students. Although prevalence rates for men are four times higher (47%) than those for women (12%), rates for men are currently decreasing while rates for women are increasing. Prevalence rates for Native Americans and Caucasians are higher than for African Americans, Latinos, and Asian Americans. Prevalence rates of cigarette smoking and other tobacco use continue to rise for both adolescents and adults in developing countries. The leading consumer of cigarettes worldwide is China, where current estimates indicate that approximately 300 million people (or 67% of the population) smoke cigarettes.

Health Effects

Cigarette smoke contains over 4,000 substances, including at least 50 carcinogens. Levels of tar and nicotine in cigarettes have decreased in the past few decades; however, levels of certain carcinogens have increased. Cigarette smoking is the major cause of chronic bronchitis and emphysema. Approximately one fifth of heart disease-related deaths are attributable to cigarette smoking. Lung cancer

caused by smoking is currently the leading cause of cancer deaths in the United States. Smoking also contributes to the development of at least 10 other types of cancer, including cancers of the oral cavity, larynx, esophagus, pancreas, stomach, bladder, and cervix.

Individual Differences in Initiation and Progression to Dependence

Recent literature indicates that certain cultural, genetic, and other factors may provide important information about causes of smoking initiation and progression to nicotine addiction.

Cultural Factors

Prevalence rates for cigarette smoking also have shown important ethnic and gender differences. For example, smoking initiation is more common among White high school students than among non-White students. This discrepancy is especially pronounced in adolescent females. Over two times as many White females smoke compared to African American females. Ethnic and gender differences in risk factors for initiation may include differential effects of peer and family influence and different perceptions of the negative consequences of smoking. Different cultural expectations from smoking may also contribute to these differences; for example, White female adolescents may be at increased risk due to expectancies that smoking helps control weight and mood.

Personality Factors

Researchers have not been able to identify an addictive personality or a group of personality factors that are common to all cigarette smokers. However, certain personality traits are consistently associated with smoking behavior, including higher stress, lower arousal, higher impulsivity and sensation seeking, and neuroticism.

Genetic Factors

Results from family, adoption, and twin studies indicate that smoking initiation results largely from genetic influences (about 50–60%) and shared environmental influences (about 20%, higher for adolescent onset). Factors contributing to progression to nicotine dependence are primarily genetic (about 70%). Current research on candidate genes for nicotine dependence has focused on genes that may influence the rewarding effects of nicotine, craving for nicotine, and sensitivity to nicotine.

Treatment

Treatment for nicotine dependence includes self-help, psychological, and pharmacological interventions. Unaided attempts to quit have shown less than a 10% success rate in leading to long-term abstinence. Advice from a physician has been found to lead to cessation rates of up to 10%. Behavioral therapy alone has demonstrated quit rates of 20%. The most promising results have been shown by combined use of medication and behavioral therapy.

Psychological interventions for quitting smoking include psychoeducation (information about smoking and health, quit strategies, and group discussion), behavioral skill training (monitoring situations, practicing cigarette-refusal skills, and relaxation techniques), and cognitive exercises such as reframing thoughts about smoking and smoking situations.

The most common pharmacological treatment used for nicotine addiction is nicotine replacement therapy (NRT). NRT involves administration of nicotine in various forms, including a skin patch, a nasal spray, an oral inhaler, and a chewing gum. These medicinal forms of nicotine prevent symptoms of nicotine withdrawal without inducing the reinforcing effects of smoking. Long-term (6–12 months) abstinence rates for treatment with NRT alone are about 20–25%. Higher abstinence rates may occur when several NRT methods are used together (e.g., patch and gum). Combined with behavioral therapy, long-term abstinence rates may be up to 35–40%.

Another pharmacologic treatment for nicotine dependence is bupropion hydrochloride or Zyban, the first non-nicotine agent approved for cessation of smoking. Cessation rates using bupropion range from 10% to 25%, depending on the dose. The proposed mechanism of bupropion involves reduction of craving and a decrease in the physiological symptoms of nicotine withdrawal.

Finally, researchers are currently examining the possibility of a nicotine vaccine. In animal models, antibodies specific to nicotine have been shown to alter the distribution, and thus the pharmacological effects, of the substance. The proposed vaccine may act by either reducing the uptake of nicotine by the brain or inhibiting the reinforcing effects of nicotine. This vaccine, if effective, is expected to be most beneficial to adolescents who smoke but have not yet become dependent. Other groups that may benefit from such a vaccine are adolescents who have not yet begun smoking, current smokers who are trying to quit smoking, and former smokers interested in avoiding relapse.

SOCIAL CLIMATE RESEARCH

Social climate (psychological climate, social context) is typically defined as the perceptions of a social environment

that tend to be shared by a group of people. Climate is rooted in perception ("how I see the way things are done or how people treat each other around here"). Culture refers more to the beliefs, values, and norms that comprise the interdependent experiences and practices of larger collectives ("what we—as a group—should do and why and how we do it"; Denison, 1996; Schneider, 1990). Like meteorological or atmospheric climate, social climate is relatively distinctive across groups (as the Tropics differ from the Himalayas); is dynamic or changeable within groups (like the seasons); and can influence behavior (like an individual's choice of clothing). Social climate research has grown considerably since White and Lippitt's (1960) early experiments comparing democratic, autocratic, and laissez-faire leadership in small groups of children. The concept and measurement of social climate have since been applied across widely diverse disciplines both within and outside the field of psychology.

Such diversity, and its parallel with atmospheric climate, can be demonstrated through a random sampling of recent research. Regarding distinctiveness, separate studies suggest that climates differ between support and therapy groups (Toro, Rappaport, & Seidman, 1987), between hospital units (Johnson, Rosenheck, & Fontana, 1997), and between multiuser Internet groups and face-to-face groups (Sempsey, 1998). Changes in the prevailing social climate have been seen as important in attitude assessment, such as in changing attitudes towards women (Twenge, 1997), and important to clinicians who modify services to fit social trends (Lyth, 1990). Studies of climate change have ranged in subjects from animal behavior (e.g., lizard aggression; Klukowski & Nelson, 1998) to organizations (e.g., small colleges; Oakley, 1997). A positive work climate has also been shown to relate to behavior or productivity (Brown & Leigh, 1996).

Researchers have developed questionnaires assessing social climate in diverse settings and content areas. These include family settings (see Knight & Simpson, 1999), adolescent peer groups (Simpson & McBride, 1992), organizational wellness (Bennett & Lehman, 1997), university teaching environments (Mateo & Fernandez, 1995), organizational learning (cf. transfer of training climate; Bennett & Lehman, 1999a), among the institutionalized elderly (Fernandez-Ballesteros, Montorio, & Fernandez de Troconiz, 1998), work-group use of alcohol (Bennett & Lehman, 1998), and hospital wards (Moos & Lemke, 1996). Perhaps the most studied aspect of climate is social cohesiveness (group pride and interdependence; Mullen & Copper, 1994).

Dimensions of Social Climate Research

Given this diversity, it helps to identify the important dimensions of social climate research. Moreover, recent emphasis on self-report measures is often not based on strong theory or methodology. Theory, measurement, and the new direction of research in social climate can benefit from some taxonomy. Six different dimensions are used here (Figure 1). These are (1) level of analysis issues (whether method/theory is sensitive to multilevel effects); (2) temporality (sensitivity to change and developmental processes); (3) type of setting (whether climate applies to one or many settings); (4) the dimension or domain studied; (5) consideration of social health; and (6) homogeneity (e.g., agreement, diversity, or multicultural processes).

Levels of Analysis

As described by Dansereau and Alutto (1990) and by Klein, Dansereau, and Hall (1994), the measurement of climate may be based on individual perceptions often referred to as psychological climate (Level 1). These perceptions may be aggregated by summing or averaging scores, such as across members of a work group or classroom (Level 2). Multiple groups can be combined into collectives such as work departments or schools (Level 3). These may be aggregated into microsocietal entities such as organizations or school districts (Level 4), which may then be combined into higher level or macrosocietal entities—for example, the state of an industry, profession, or educational system (Level 5). Researchers have focused on Level 1 measurement, but recent efforts have used multilevel statistical techniques (e.g., hierarchical linear modeling; Bryk & Raudenbush, 1992). Examples include group-level cohesiveness, which predicts courteous behaviors (Kidwell, Mossholder, & Bennett, 1997), and neighborhood cohesiveness/social integration, which predicts taking safety precautions against crime (Rountree & Land, 1996). Levels of analysis are critical for assessing such things as cross-level congruence and codetermination, as well as bottom-up versus top-down processes (see Kozlowski & Salas, 1997).

Temporality

Group facilitators and coaches use models of group development that anticipate and guide shifts in social climate (e.g., forming, storming, norming, and performing; Tuckman, 1965). Organizational psychologists are increasingly being called on to improve the climate of a business or workplace (e.g., Schneider, 1990). Despite strong interest in application of ideas of climate change, little has been written about the temporal qualities of climate. For example, how do the boundaries and shape of social climate change over time? Which dimensions are changeable and at what rate? Answers to such questions may come from related studies of time in work groups (McGrath, 1990) and dynamic systems in social psychology (Vallacher & Nowak, 1994).

Setting

As just seen in the review, researchers examine social climate within diverse settings. Thus, measures are often developed for specific rather than universal application. Pre-

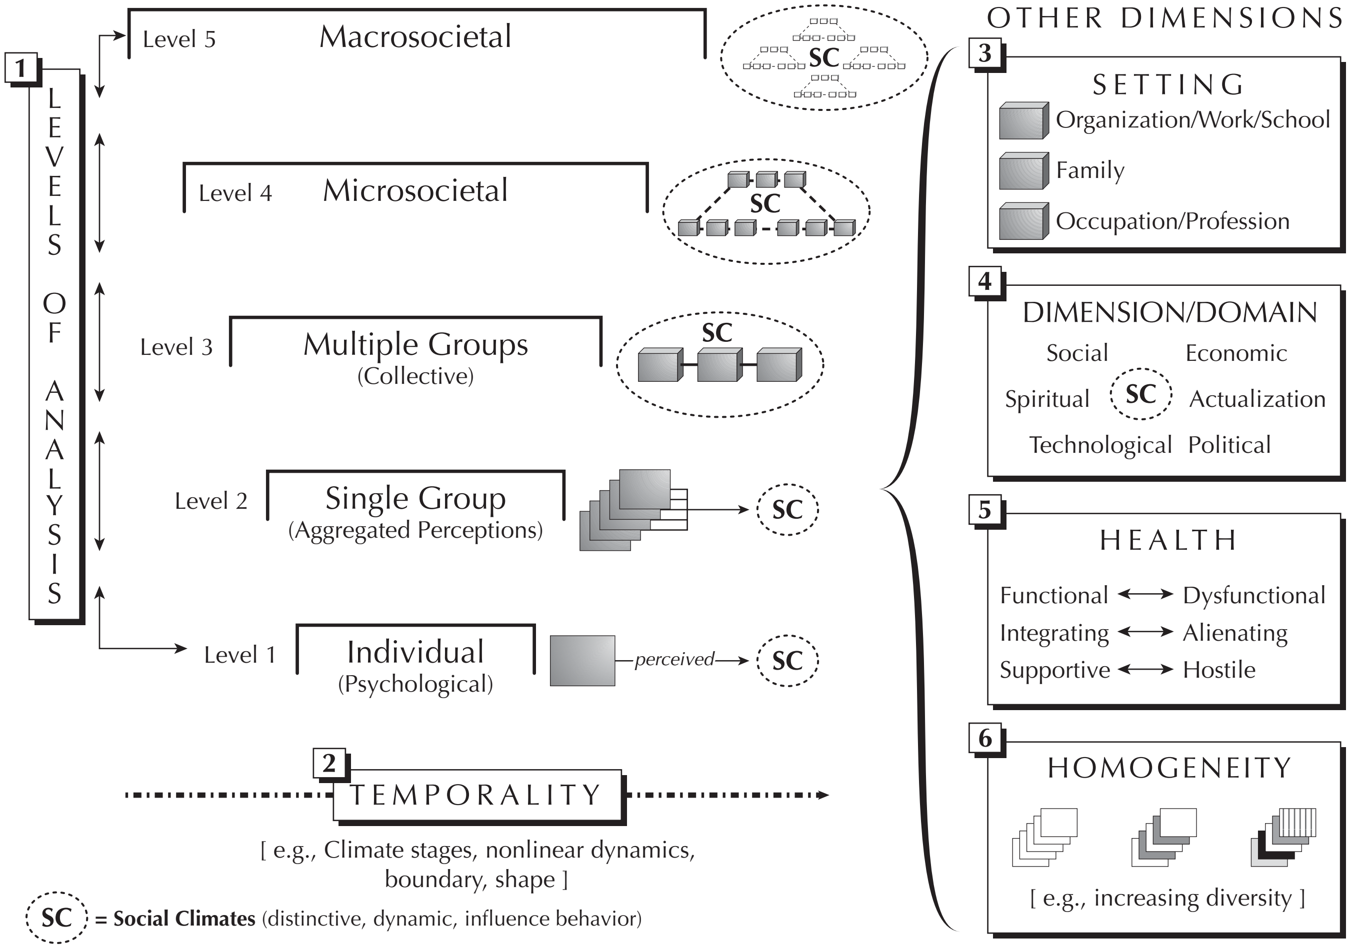

Figure 1. Six dimensions of research into social climates.

dominantly, these have been in organizations (e.g., service, safety, and team climate), schools (e.g., social order, study climate), family settings (e.g., affective involvement, conflict), and some specific occupations or professions (e.g., academic and healthcare).

Dimensions and Domains

Most studies of social climate view it as multidimensional, with anywhere from 3 to 10 different factors. Factor analysis is often used to support multidimensionality. Kopelman, Brief, and Guzzo (1990) view all work climates as having five core dimensions: goal emphasis, means emphasis, reward orientation, task support, and socioemotional support. Denison (1996) also derives five dimensions found across both culture and climate research: structure, support, risk, identity, and standards. It should be noted that social climate overlaps with group-level perceptions in a variety of domain and event areas. Domains include spiritual (church, prayer group), sociotechnical (Internet, shared equipment), economic (distress due to job scarcity), actualization/leisure (self-help groups, shared hobbies), and political (common leaders, partisan loyalty). Researchers have also examined the climate of events or occasions within domains (e.g., holiday seasons, trade shows, business meetings, competitive events, conventions).

Social Health and Safety

Social support or health is a dimension found or implied in nearly all climate measures, and many climate researchers explore the degree to which a group is healthy or unhealthy. For example, studies examine the degree to which the social climate supports substance use (e.g., smoking in adolescents [Byrne & Reinhart, 1998]; drinking at work [Bennett & Lehman, 1999b]). Studies of social integration (vs. alienation), social health, and workplace safety (Cox, 1998) also examine social climate.

Homogeneity and Heterogeneity

Recent research suggests that climate may not always be perceived in the same way by the people who comprise the social group. From a methodological standpoint, researchers have

yet to determine how much within-group variability is due to error variance, to actual disagreement, or to some other critical factor such as cultural or gender diversity. Here, the study of social climate borrows from studies of perception within groups (Gigone & Hastie, 1997), measurement of agreement (James, Demaree, & Wolf, 1984), and the field of relational demography (Harrison, Price, & Bell, 1998).

SOCIAL COGNITION

The field of social cognition is concerned with the cognitive activity that mediates and accompanies social behavior. It provides an analysis of how stimulus information is initially encoded, organized (and transformed) in memory, and drawn on as the person moves through the social world.

Social cognition, which is neither a single theory nor a narrow empirical domain, refers instead to a particular conceptual level of analysis used in the joint explanation of human thought and social behavior. The level of analysis is molecular rather than molar. Theorists working within this orientation use mental constructs at the level of individual thoughts, categories, and concepts. These constructs are abstract enough to encompass a wide range of content domains (e.g., thoughts about people, traits, situations, animals, and works of art). Most researchers in this field, though mentalistic, do not restrict themselves to the study of conscious thought. The mental constructs are usually defined so as to leave open the question of consciousness.

Workers in the fields of cognitive psychology, psycholinguistics, and artificial intelligence became preoccupied with higher order cognitive processes and grew interested in explaining complex types of human information processing, such as the comprehension and retention of stories, action sequences, and other thematically coherent stimulus ensembles.

The concept of a schema provided the initial meeting ground for the social and cognitive research groups. The elements of our cognitive world do not exist in some random, unrelated array. Rather, they are interassociated into higher order structures.

The schema concept was quite congenial to social psychologists because they already had been using a number of schema-like concepts. These included such terms as stereotype, norm, value, attitude, and implicit personality theory. Some workers in social cognition have developed taxonomies of schemas to aid in establishing conceptual similarities across different topics. Some of the categories proposed are person, role, event, trait, pictorial (or visual), and social group. Taxonomies have also been developed from the cognitive-process point of view that classify schemas in terms of their conceptual properties.

Information-Processing Perspective

The social cognition approach views the human mind as an information-processing system. Information is received from the stimulus world, processed through the cognitive system, and drawn on when engaging in social behavior.

One stage of information-processing deals with the problems of encoding and organization. A second information-processing topic area deals with the problem of cognitive retrieval. What determines the flow of thought, and how do we access prior information and inferences when engaging in social behavior?

There is also the problem of implicit retrieval that occurs in the case of more or less spontaneous social responses. A search for previously acquired information can be bypassed when a behaviorally relevant schema is available.

A third category of issues has to do with information integration. People often face situations for which they have no adequate schemas. Especially when people anticipate encountering such situations often in the future, it is in their interest to develop a new schema to deal with the kinds of variations found in this setting.

A fourth topic area is response selection. How do people survey their response alternatives, tacitly select one, and behaviorally implement it? Communication context and knowledge of the audience's point of view can affect how and when cognitive responses are transmitted.

Unresolved Issues

Social cognition researchers have generally avoided the issue of how cognitive systems are energized. An allied concern is the role of cognitive systems in regulating motivational energies.

Social environments are exceedingly complex. The amount and diversity of information contained in a social interaction are enormous. How does the person arrive at a particular organizational mode? Does the mode fluctuate from one point in the conversation to another, and is it possible to encode (and store) the information in two or more ways simultaneously? This kind of question becomes salient when adopting the level of analysis characteristic of the social cognition perspective.

T. Ostrom

SOCIAL CONSTRUCTIONISM

Social constructionism is an account of knowledge-generating practices, scientific and otherwise. At this level, constructionist theory offers an orientation toward knowledge making in the psychological sciences, a standpoint at considerable variance with the empiricist tradition. At the same time, social constructionism contains the ingredients of a theory of human functioning; at this level, it offers an alternative to traditional views of individual and psychological processes. Constructionist premises also have been extended to a variety of practical domains, opening new departures in such fields as therapy, organizational management, and education.

Assumptions and Antecedents

Social constructionism is not wedded to a fixed set of principles. Rather, it is more properly considered as a continuously unfolding conversation in which various positions may be occupied, elaborated, or vacated as the dialogue proceeds. Several themes are typically located in writings that identify themselves as constructionist. It is typically assumed that accounts of the world—scientific and otherwise—are not dictated or determined in any principled way by what there is. Rather, the terms in which the world is understood are generally held to be social artifacts, products of historically situated interchanges among people. Thus, the extent to which a given form of understanding prevails within a culture is not fundamentally dependent on the empirical validity of the perspective in question but rather on the vicissitudes of social process (e.g., communication, negotiation, communal conflict, rhetoric). This line of reasoning does not detract from the significance of various forms of cultural understanding. People's constructions of the world and self are essential to the broader practices of a culture, justifying, sustaining, and transforming various forms of conduct.

Simultaneous to the developments in social thought and literary theory, political events of the 1960s stimulated large numbers of scholars to reconsider the traditional scientific claims of value neutrality. With increasing degrees of sophistication and indignation, scholars influenced by critical school formulations demonstrated ways in which ordinary and unchallenged assumptions within the sciences lent themselves to unfair distributions of economic resources and political power. These concerns expanded exponentially as the feminist movement began to flourish, and inquiry mounted into the injurious implications of taken-for-granted assumptions embedded within theories, methods, and policies of the sciences. Scholars also became increasingly vocal over the ways in which social science assumptions carried racist values, championed selfish or narcissistic ways of life, or served as a means of subverting non-Western ways of life. For many such scholars, the works of Michel Foucault, which demonstrated the relationship between regimes of language and power relations, also proved pivotal. All of these endeavors demonstrated the extent to which accounts of the world are inseparable from broader social practices.

The Social Construction of Knowledge

The social constructionist view favored by this composite of developments has begun to furnish a replacement for traditional empiricist accounts of psychological science. In the process of this replacement, one may discriminate between two phases: deconstructionist and reconstructionist. In the former phase, pivotal assumptions of scientific rationality, along with bodies of empirically justified knowledge claims, are placed in question. Essentially, this work represents an elaboration and extension of the early antifoundationalist arguments, now informed by the additional developments within the literary and critical domains.

Within the reconstructive phase, the chief focus is on ways in which scientific inquiry, informed by constructionist views, can more effectively serve the society of which it is a part. Although such issues are at the forefront of contemporary discussion, more a matter of debate than decision, several broad themes are apparent. When applied to the domain of psychological study, they suggest the following.

1. *Practical empiricism.* Constructionists are critical of traditional claims that scientific knowledge, in the form of propositional networks, can yield logically derived predictions in a variety of practical settings. However, this is not to negate the possibility of practical prediction itself. Thus, for the constructionist the enormous array of empirical technologies is largely misused, serving primarily those who seek to sustain substantively empty theories within a community of scientific peers. In contrast, observational techniques, measuring devices, and statistical technologies can be used effectively to assess current conditions (e.g., cultural well-being, contours of conflict, homelessness), to evaluate the efficacy of various programs (e.g., community shelters, job training, conservation), and to draw trend lines for deliberating the future (e.g., planning for day care needs, drug-counseling facilities, employment-retraining centers). Of course, the terms of such study would always be culturally constructed, but there is nothing about constructionism that demands the abandonment of intelligibilities (or ways of life) by virtue of recognizing their communally constituted character.

2. *Conceptual innovation.* Although constructionism favors a shift of empirical efforts from the decontextualized setting of the laboratory to sites of practical activity, it also thrusts theoretical activity into a new and more significant role. For the constructionist, the

traditional view that theories should provide accurate accounts of the world is placed in question. Rather, it is argued, language gains its meaning and significance from its function within relationships. Language is a major means by which relationships are carried out. Thus the theoretical language of psychology should be evaluated not in terms of verisimilitude but in terms of its contribution to cultural life. From this standpoint, the practical value of theoretical formulations does not await the drawing of derivative predictions; rather, as psychological discourse gains intelligibility within the culture (through education, the media, the mental health professions, and the like), it becomes a usable resource within the sphere of daily relationships. Thus, scholarly work in psychology—in the form of innovative theorizing—may have enormous potential for the society. For as new theoretical lenses are made available, new options may open in problem domains of long standing. New ways of understanding conflict, of seeing the educational process, of appreciating group differences, and so on, may become available as a cultural resource. This is not to abandon empirical work at the level of scholarly inquiry. However, research procedures at this level primarily serve purposes of vivification; they give theoretical ideas—both descriptions and explanations—a sense of palpability. They enable others to see the world in particular terms.

3. *Valuative reflection.* In the empiricist tradition, the primary criteria for critical assessment of scientific work were methodological. The chief question to be asked of a given formulation was whether it was a valid account of the phenomenon. For the constructionist, however, the crucial question to be asked of a theoretical formulation is how it can or will function within the broader society. What institutions and actions the theory sustains, what is challenged by the formulation, and what new options are opened are all questions of paramount concern. To address such questions fully requires deliberation of a moral and political character. Does a given formulation sustain desirable or undesirable forms of cultural life? Does it undermine cherished institutions? Does it promote human welfare? Such questions necessarily move scientific deliberation from the realm of *is* to *ought.* From the constructionist standpoint, such deliberation should become a normal part of scientific training, and contributions to the dialogue should play a featured role in the books and journals of the field.

Social Constructionist Inquiry in Psychology

Social constructionist views not only provide metatheory for the science of psychology but also are reasserted at the level of psychological theory itself. That is, in providing an account of the knowledge-making activities of scientists, they also offer a way of understanding patterns of human action more generally. Three active areas of inquiry are illustrative.

Major efforts are devoted to exploring the discursive construction of reality. Here investigators attempt to demonstrate the processes by which persons construct the world and self through language. Typically employing techniques of discourse analysis, many investigators explore patterns of existing construction (e.g., cultural assumptions about the developing child); the media construction of homosexuality; the public construction of acquired immunodeficiency syndrome (AIDS); or the available discourses for describing intelligence, the environment, or cultural conflict. Much of this research is used for purposes of generating social change. By elucidating common assumptions, investigators hope that people may be emancipated from the taken-for-granted. In contrast, other investigators attempt to demonstrate the limits of our constructive frameworks. For example, Smedslund attempts to axiomatize cultural understandings of the mind, arguing that it is impossible for cultural participants—including scientific psychologists—to formulate an intelligible proposition that violates these assumptions. Still other scholars are concerned with the ways in which the cultural discourses and conversational positions are used to construct personal identity in ongoing relationships.

A second line of constructionist inquiry is into psychological processes themselves. However, rather than viewing such processes as universal and transhistorical, constructionists are more centrally concerned with individual functioning as it is socially constituted, both in history and culture. How is it that people come to account for their mental life in the ways they do and to perform in such a way that these constructions are made real to both self and others? Historical analysis thus attempts to reveal the ways in which psychological processes were constituted in previous eras and to assess the cultural conditions either favoring a given constitution of the mental world or rendering it dysfunctional.

SOCIAL DESIRABILITY

Social desirability is the tendency for individuals to present themselves in a generally favorable fashion. Within the fields of psychological testing in general and personality assessment in particular, the concept of social desirability has fueled heated debates for decades. Arguments have focused on the definition of social desirability, its pervasiveness, problems it presents for the interpretation of psychological tests, and methods for its control.

Social desirability has variously been defined as the tendency to give culturally sanctioned and approved responses (Crowne & Marlowe, 1960), to provide socially desirable responses to statements in self-description, or to describe oneself in terms judged as desirable and to present oneself favorably. Noted here is an emphasis on a style of responding irrespective of the specific personality content dimension to be measured by a psychological test. Consequently, a potential problem for a self-report personality test is whether an elevated score represents a high standing on the test's content dimension or a greater tendency to present oneself favorably. For example, does a high score on a particular self-report scale of ambitiousness reflect a test taker's true level of ambitiousness or the respondent's tendency to answer test items in terms of social desirability? The existence of such ambiguous interpretations has generated substantial debate and research.

Research indicates that there are two facets to social desirability (Paulhus, 2002). The first aspect concerns the self and a belief in one's own ability. Phrases used to label this facet include sense of own general capability and egoistic bias. The second component focuses on an orientation toward others, and its labels have included interpersonal sensitivity and moralistic bias. It should be noted that individual scales designed to assess social desirability may measure either or both of these facets.

Some assessment experts believe that self-report tests that have been developed without explicit attempts to minimize the influence of social desirability could be saturated with this stylistic influence. Consequently, any interpretations from such tests are ambiguous and suspect. In contrast to this perspective is the belief that social desirability is itself a personality variable that may be a legitimate component of individual differences. For example, it might be argued that a strong belief in one's own abilities (i.e., social desirability) is a legitimate aspect of the concept of ambitiousness. This, however, then presents a problem: If social desirability is a feature of many different constructs of personality (e.g., ambitiousness, friendliness, neatness, etc.) and social undesirability (i.e., negative social desirability) is a facet of various components of psychopathology (e.g., depression, hostility, alienation), then these constructs are not truly and legitimately independent and should not be theorized, measured, or reported as such.

Various methods have been proposed for coping with social desirability in self-report tests. First, a forced-choice response format could be used for a test. Response options for any test item would then be matched for social desirability. Second, test items could be selected for a scale based on those items being more strongly representative of the psychological concept of interest than social desirability. This would involve a test construction strategy that used some form of item selection from an initial larger pool of test stimuli in which items had been somehow measured for appropriate content and inappropriate response bias (e.g., social desirability). Third, test instructions could be tailored to reduce the likelihood that test takers will be influenced by social desirability. For example, a statement to test takers indicating that the test contains an index for monitoring inaccurate responses could serve to reduce socially desirable responding. Fourth, social desirability could be statistically removed from the score generated on the test. This would require the use of a social desirability scale, the score on which would then be used to adjust the initially obtained score for the psychological concept of interest.

Even though the rancorous debates of the 1960s concerning social desirability have mellowed into more polite disagreements, heated arguments do flare up intermittently. Test developers and users are well advised to be aware of the issues. To construct tests of personality or psychopathology without due consideration of noncentral influences on test responding (e.g., social desirability) is to flirt with theoretical and operational disaster.

SOCIAL FACILITATION

The question of social facilitation research is how the presence of another person affects performance. If you play a musical instrument alone or in front of an audience, is your performance typically better or worse? If you type with no one around, compared to someone else merely working in the background or observing you, how do these conditions affect both the speed and accuracy of your typing?

Allport (1924) first used the term *social facilitation* for "an increase in response merely from the sight or sound of others making the same movement" (p. 262), although it now refers to either an increase or a decrease in response and from a person who might not be making the same movement. Vaughan and Guerin (1997) argued that an earlier experiment by Triplett (1898), commonly said to be the first in social facilitation, was not related.

The factors affecting performance in the presence of another person were comprehensively delineated by Allport (1924) and Dashiell (1935) and include competition (rivalry), modeling, encouragement or social reinforcement, arousal, monitorability, imitation, group membership, dis-

traction, and evaluation (Guerin, 1993). There is evidence for each of these, and they have separate research literatures.

Social facilitation research has probably held together as a distinct topic only because of the work of Robert Zajonc. Zajonc (1965) first hypothesized that new or poorly learned actions would be made worse by the presence of another person, whereas well-learned actions would be facilitated. For example, an accomplished flute player would perform better with other people present, whereas a poor or beginner flute player would do worse. This formed a simple 2×2 experimental design with participants performing alone or with someone else present and performing either a well-learned or a new behavior. At least 15 theories for this were proposed between 1965 and 1993, and at least 100 tests have been based on this simple design (Guerin, 1993).

The second hypothesis of Zajonc (1965) was that apart from the factors mentioned earlier, there might still be effects from just the mere presence of another person, a term first used by Burnham (1910, p. 766). This negative definition led researchers to attempt to control for all other factors while measuring performance changes. However, it was difficult to control for so many other factors, and only 91 out of 313 studies had suitable controls (Guerin, 1993). The most common fault was to have an experimenter present in the Alone condition.

It has been argued that this whole research endeavor was unsuccessful not only because all the factors could not easily be controlled, but also because a single measure was typically used as evidence for both social facilitation and the alternative theory (Guerin, 1993). Theories were needed of what mere presence was rather than what it was not so that independent measurements could be made of performance and the theoretical mechanism.

Of the reliable effects that have been found using the simple designs and single measures, there are two main ones. First, when someone else is present, people tend to behave in accordance with socially expected standards of performance. This leads to conformity with what they think the experimenter wants them to do, which is usually to try harder at their performance and to do well, but only when they believe that they can be monitored (when there can be consequences) by the experimenter. The second main effect found is an increase in alertness or attention. That is, people are more attentive to what is going on, more rule-governed or verbally governed in their behavior, when someone is present than when they are alone. This impacts on their performance in different ways: If the task is difficult or new, they will do worse if they are paying attention elsewhere (Sanders, 1984); if the task is easy, they might be more relaxed if they have time to watch what people are doing (Guerin, 1993).

There is also a large social facilitation research literature with nonhuman animals. The findings seem to reflect what the species normally does alone or in groups (Guerin, 1993). Normally solitary animals (cats) will become fearful if put in the presence of another animal and will therefore reduce feeding but increase other aggressive or defensive behaviors. Animals that normally live in groups (rats) will tend to interact socially and eat less but play more when put together. Chicks put together in groups become less fearful but do not interact and therefore eat more than when alone.

The problem, then, is similar to that suggested for human studies. If only a single measure is used, such as the facilitation or inhibition of feeding, then there are contradictory findings: Rats eat less in groups but chicks eat more. If the whole context or social ecology is measured, the contradictions disappear: Rats use their time together to groom and play and therefore stop eating, whereas the chicks reduce their fear activities when in groups and spend the extra time eating. The problems of social facilitation research with humans also come down to this: that too much reliance has been made of simple designs and sparse measures. It is not enough to know that people type less when someone else is present with them; we need to measure what they are doing instead. It has also been argued that all behavior is social for humans, even when alone (Guerin, 2001).

SOCIAL INFLUENCE

Social influence may be defined as the capacity to affect the outcomes of oneself, others, and the environment. The use

of social influence may be direct (within interpersonal interaction) or indirect (through group norms and values). All human interaction involves influence. There are three different perspectives on social influence: the trait factor, dynamic interdependence, and the bases of power.

Trait-Factor Perspective

The trait-factor approach to social influence may be traced to Aristotle, whose rhetoric dealt at some length with the characteristics of an effective influencer and gave detailed advice on the techniques of persuasion (Johnson & Johnson, 2003). From the trait-factor point of view, social influence is a function of the characteristics of: (1) the person exerting the influence, (2) the person receiving the influence, and (3) the influence attempt itself. This view is based on two assumptions. First, a person's traits—not circumstances, fortune, or opportunities—explain the person's behavior (certain people are born influencers and others are not). Second, people are rational in the way they process information and are motivated to attend to a message, learn its contents, and incorporate it into their attitudes. The major post–World War II application of the trait-factor approach to social influence was the Yale Attitude Change Program headed by Carl Hovland (Hovland, Lumsdaine, & Sheffield, 1949). Most of the research in this program focused on the effects of a single attempt to influence an audience with a message delivered through the mass media. When a politician gives a speech to an audience, for example, the contact between the communicator and the receiver of the communication is brief and is not repeated. Moreover, the communication is one-way; there is no interaction between the two parties. Because single instances of one-way communication are essentially static, a trait-oriented theory is quite helpful in analyzing them.

Much of the post–World War II research on social influence stemmed from Hovland's wartime studies of propaganda and was organized around the theme question, Who says what to whom and with what effect? Investigators have usually broken this question down into variables relating to the source (the characteristics of the communicator), the message (the characteristics of the communication), and the receiver (the characteristics of the person receiving the message). Social influence occurs when a credible and attractive communicator delivers an effectively organized message to a vulnerable or influenceable audience.

The two most researched aspects of communicators are credibility and attractiveness. The credibility of communicators depends on their perceived ability to know valid information and on their perceived motivation to communicate this knowledge without bias. More specifically, credibility depends on objective indicators of relevant expertise, perceived reliability as an information source, lack of self-interest in the issue, warmth and friendliness, confident and forceful delivery of the message, and considerable social support from others. The attractiveness of communicators depends on their facilitation of the receiver's goal accomplishment, physical appearance, perceived similarity, perceived competence, warmth, and familiarity.

Messages that inspire fear with specific instructions for action, messages that acknowledge opposing viewpoints, and the size of the discrepancy between the content of the message and the receiver's position all promote social influence. Influence attempts are aimed at a receiver. The receiver's self-esteem, present attitudes, forewarning of the intention to influence, practice in defending a position, and intelligence all affect the success of an influence attempt. Furthermore, actively role-playing a previously unacceptable position increases its acceptability to the receiver.

The trait-factor approach to social influence is weak both logically and empirically in situations in which two or more individuals are constantly interacting.

Dynamic-Interdependence Perspective

Dynamic means in a constant state of change; *interdependence* means that each member's actions affect the outcomes of other members. The dynamic-interdependence view of social influence posits that influence exists in relationships, not in individuals; that is, a person cannot be an influencer if there is no influencee (Johnson & Johnson, 2003). For influence to be constructive, it must occur in a cooperative (not competitive) context. In a cooperative context, influence is used to maximize joint benefits and promote the achievement of mutual goals. In a competitive context, influence is used to gain advantage and promote one's own success at the expense of others. Influence attempts in a competitive context result in resistance. *Resistance* is the psychological force aroused in an individual that keeps him or her from accepting influence.

When individuals work together to achieve mutual goals, social influence is inevitable. They must influence and be influenced by each other, each modifying and adjusting his or her behavior to respond to what the other person is doing. The speed of conversation, the attitudes expressed, and the phrasing of messages are all influenced by the others with whom one is interacting. The use of influence is essential to all aspects of relationships. Goals cannot be established, communication cannot take place, leadership cannot exist, decisions cannot be made, and conflicts cannot be resolved unless there is mutual influence. The degree of influence is dynamic in that it constantly changes as the individuals make progress in obtaining their goals, as their costs (in energy, emotion, time, etc.) of working collaboratively vary, and as other relationships become available in which the goals might be better achieved. If the individuals make progress toward achieving the goals, the costs of working together are low, and no other relationships are as rewarding, then the ability of the individuals involved to influence each other increases.

Bases-of-Influence Perspective

According to social exchange theory, influence is based on the control of valued resources. The more an individual wants a specific resource, the more power the people who control the resource have over him or her. Different types of influence can be specified based on what types of resources are under a person's control (Raven, 1992). There are six possible bases for a person's social influence: one's ability to reward, one's ability to coerce, one's legal position, one's capacity as a referent with whom others wish to identify, one's expertise, and one's information. Each of these sources (reward, coercion, legitimacy, referent capacity, expertise, information) enables one to influence others.

SOCIAL ISOLATION

Social interaction is integral to mental health across development. Lack of social interaction, or social isolation, not only is a painful experience but also can negatively impact child development. For infants and young children, lack of interaction with a primary caretaker can lead to marked delays in cognitive, socioemotional, linguistic, and motoric development. Furthermore, dysfunctional parent-child interaction patterns can contribute to child social incompetence and social isolation. For school-age children and adolescents, peer interaction becomes an increasingly important socializing agent that provides them with opportunities for social, emotional, and cognitive development. Through interpersonal interaction, children develop the skills of collaboration, perspective taking, empathy, and social competence, which help to promote prosocial behavior and decrease inappropriate, immature, or annoying behavior. The development of these social skills also contributes to children's healthy academic and emotional adjustment, decreasing the likelihood of negative social experiences, such as peer neglect or rejection and isolation.

Social isolation can lead to feelings of loneliness, low self-esteem and alienation, negative self-concept and powerlessness, increased shyness and anger, decreased creativity, depression, social and academic difficulties, and in some cases delinquent behavior and violence. Recent studies suggest that social anxiety may be a precursor to social isolation and that the loneliness that accompanies social isolation uniquely contributes to more severe emotional problems. Additionally, distinctions have been drawn between children who are deliberately isolated by their peers because of cognitive immaturity and inappropriate behavior and children who are passively or anxiously withdrawn. Different characteristics and outcomes may be related to these two dimensions of social isolation, which would also have implications for treatment. Although early developmental research suggested that many withdrawn children outgrow their isolate behaviors, there is evidence that for some children, social isolation is an enduring experience. For these children, the negative effects of social isolation may persist beyond childhood, leading to maladjustment in adolescence and adulthood, including poor educational attainment, occupational status, and psychological well-being.

Socially isolated children seldom initiate contact with others or respond to the invitations of others. These children tend to be ignored and neglected by their peers due to their lack of a conspicuous presence. Recent research regarding the effects of technological advances, such as the Internet, on adjustment suggests that these advances offer new outlets for socialization for isolated youth, although they may not decrease emotional difficulties and loneliness and may lead to weaker social ties. Identification and treatment of social isolation often occurs within academic settings where teachers become aware of withdrawn children's social difficulties. Socially isolated children can be identified through observation or sociometric measures. Additionally, children's self-perceptions of social support and social networks can provide information about experiences of social isolation.

As a treatment for social isolation, social skills training targets deficiencies in social skills performance, such as the ability to interpret interpersonal situations correctly and seek entry into a peer group competently. Such training helps socially withdrawn children learn skills for developing and maintaining gratifying relationships with others. Added components to social skills training interventions may include pairing socially isolated children with socially competent peers, rewarding children for positive social behavior, and addressing any emotional experiences of socially isolated children that may be inhibiting social interaction. Within these intervention approaches, socially isolated children have an opportunity to learn positive social skills, initiate social interactions and friendships, and learn ways to cope with negative affect.

SOCIAL NEUROSCIENCE

Neuroscientists and cognitive scientists have collaborated for more than a decade with the common goal of understanding how the mind works. The focus of this work has been relatively restricted, however, as more complex aspects of the mind and behavior that involve conspecifics and their products (e.g., norms, culture) have fallen outside of the purview of cognitive neuroscience. Social neuroscience emerged in the early 1990s to address these kinds of questions at the information-processing, neural, and computational levels of analysis (Cacioppo & Berntson, 1992).

The notion of a social neuroscience is not as oxymoronic as it might first seem. Evolutionary forces operating over thousands of years have sculpted the human genome to be sensitive to and succoring of relationships with others. Affiliation and nurturant social relationships, for instance, are essential for physical and psychological well-being across the lifespan (Cacioppo, Berntson, Sheridan, & McClintock, 2000). Disruptions of social connections, whether through ridicule, separation, divorce, or bereavement, are among the most stressful events that people endure (Gardner, Gabriel, & Diekman, 2000), and social isolation is as large a risk factor for broad-based morbidity and mortality as are high blood pressure, obesity, and sedentary lifestyles even after statistically controlling for known biological risk factors, social status, and baseline measures of health (House, Landis, & Umberson, 1988). The case of Phineas Gage in the late 1800s vividly established the importance of the frontal cortex for orchestrating normal social discourse (MacMillan, 1999), and various other cortical and subcortical nuclei involved in social cognition have now been identified (Adolphs, 1999).

Social neuroscience has emerged as a pullulating scientific perspective for several additional reasons. Theoretical insights into the mechanisms underlying social processes, as well as ways of testing otherwise conflicting theoretical accounts of social behavior, have come from theory and research in the neurosciences (Berntson, Boysen, & Cacioppo, 1993; Clark & Squire, 1998). Reciprocally, the study of social processes, including work on social factors as moderators of various specific mechanisms, has challenged existing theories in the neurosciences, resulting in refinements, extensions, or complete revolutions in theory and research in the neurosciences (Glaser & Kiecolt-Glaser, 1994). In addition, just as genetic constitution affects a wide array of social behaviors, the social environment has also been shown to shape genetic expression, neural structures, and biochemical processes (Liu et al., 1997).

In an early review, Cacioppo and Berntson (1992) coined the term *social neuroscience* and outlined several organizing principles for multilevel integrative research. The first, the principle of multiple determinism, specifies that a target event at one (e.g., a molar) level of organization can have multiple antecedents within or across levels of organization. For example, both research on individual differences in the susceptibility of the endogenous opioid receptor system and on the role of social context have contributed to our understanding of drug abuse.

The second, the principle of nonadditive determinism, specifies that properties of the whole are not always readily predictable from the properties of the parts. In an illustrative study, the effects of amphetamine on behavior of nonhuman primates were indeterminate until each primate's position in the social hierarchy was considered (Haber & Barchas, 1983). The inclusion of this social factor revealed an orderly relationship, such that amphetamines increased the dominant behavior in primates high in the social hierarchy and increased submissive behavior in those low in the social hierarchy.

The third, the principle of reciprocal determinism, specifies that there can be mutual influences between microscopic (e.g., biological) and macroscopic (e.g., social) factors in determining behavior. For example, not only has the level of testosterone in nonhuman male primates been shown to promote sexual behavior, but the availability of receptive females influences the level of testosterone in nonhuman primates (Berntstein, Gordon, & Rose, 1983). The implication of this and the preceding principles is that multilevel analyses spanning neural and social perspectives contribute to scientific investigations of complex human behavior and foster more comprehensive accounts of cognition, emotion, behavior, and health.

SOCIAL PSYCHOPHYSIOLOGY

Social psychophysiology is characterized by the use of noninvasive procedures to study the relationships between actual or perceived physiological events and the verbal or behavioral effects of human association. The field represents the intersection of social psychology and psychophysiology. Social psychology, the older of the two spawning disciplines, is directed toward understanding the reportable and behavioral effects of human association, whereas psychophysiology employs noninvasive procedures to study the interrelationships between physiological events and a person's reportable or overt behavior. Social psychology, generally partitioned into conceptual areas of research (e.g., attitudes, aggression, altruism), is replete with abstract theories based largely on verbal data. Psychophysiology, in contrast, is generally partitioned into anatomical areas of research (e.g., cardiovascular gastrointestinal) and is laden with sophisticated physiological measures, instrumentation, and observations with uncertain psychological significance. Social psychophysiology has emerged from these disparately focused disciplines for the purposes of understanding the psychological significance of physiological events and explaining complex behaviors in biological terms.

The perspective on human behavior epitomized by social psychophysiology is quite old. It dates back to at least the third century B.C. Articles bearing the imprint of a social psychophysiological perspective began appearing in the psychological literature in the 1920s with reports about the changes in the breathing of poker players when they were bluffing and about the galvanic skin responses (GSRs) of students finding themselves possessing attitudes shared by few peers. The first summary of empirical research in social psychophysiology was published by Kaplan and Bloom in 1960. The review dealt with the physiological concomitants of social status, social sanction, definition of the situation, and empathy. An optimism was expressed that the field of social psychophysiology had come of age. At about the same time, John Lacey published a critical and cogent review in which he argued that there was little consistency in the literature on which to build bridges between psychophysiological data and psychological constructs.

Nevertheless, investigations of the reciprocal influence of social and physiological systems began to broaden in scope and increase in number. In 1962 Schacter and Singer published their influential two-factor theory of emotions: that the sensations derived from a large and unexpected increase in physiological arousal could be experienced as widely different emotions, depending on the circumstances covarying with these sensations. Leiderman and Shapiro represented a different vein of research: Evidence was presented for the dramatic impact that social factors such as conformity pressures have on physiological responding.

The attractiveness of psychophysiological procedures was tempered, however, by three formidable barriers: (1) the paucity of conceptual links between the psychophysiological data and social psychological constructs; (2) the technical sophistication and expensive instrumentation required to collect, analyze, and interpret psychophysiological data in social psychological paradigms; and (3) the inevitable pitting of social psychological and psychophysiological procedures against one another in studies of construct validation. Three distinct strategies developed for dealing with those barriers. One strategy was simply to dismiss physiological factors as irrelevant, at least at present, to the study of social cognition and behavior, and to dismiss social factors as too molar to contribute to an understanding of psychophysiological relationships. A second strategy was to view the physiological factor important in the study of social processes as being a diffuse, perceptible change in physiological arousal. This view provided the rationale for conducting research with little or no psychophysiological recording equipment and expertise, as it followed from this reasoning that any single physiological response, or even sensitive measures of interoceptive sensations, reflected a person's physiological arousal at any given moment (cf. Cacioppo & Tassinary, 1990).

The third approach more often involved collaborative efforts by psychophysiologists and social psychologists. The strategy followed was to narrow the breadth of the social issue under investigation while increasing the depth (levels) of the analysis. For instance, rather than viewing physiological arousal as the sine qua non of organismic influences on social cognition and behavior, specific patterns of physiological responses were conceived as reflecting or influencing specific social processes. Experiments exemplifying this approach are characterized by the simultaneous measurement of multiple physiological, verbal, and behavioral responses in a single session and by interpretations that entertain highly specific, reciprocal, and (at least initially) biologically adaptive influences between social and physiological systems. Studies of the incipient and transient patterning of facial muscles during social interaction, impression formation, or social influence are illustrative.

During the past two decades, the increasing utility for investigators to be informed about various levels of human behavior ranging from the physiological to the sociocultural resulted in a convergence among the three research strategies outlined as the barriers to social psychophysiological research were overcome. The nonelectrophysiological procedures developed by earlier investigators to study the effects of arousal on social processes, for example, posed interesting questions regarding the actual physiological basis for the obtained data. Technical advances increased the accessibility of psychophysiological methods, and psychophysiologists began to grapple with the acute and chronic effects of interpersonal factors and the social context on physiology. This, in turn, led to contributions to the fields of social and health psychology. Additionally, developments in noninvasive brain imaging and cognitive neuroscience have further contributed to the bridging of the abyss between psychophysiological data and psychological constructs. Clearly, the barriers once separating biological and social approaches are no longer major obstacles to integrative, multilevel analyses of human behavior.

SOCIAL SUPPORT

The term *social support* refers to supportive relationships that arise between oneself and friends, family members, and other persons (Friis & Sellers, 1999). The concept embodies material and emotional resources that accrue through one's relationships with others (Friis & Taff, 1986). Social support results in the feeling that one is cared for, loved, esteemed, and valued or is part of a network of mutual interpersonal commitments (Cobb, 1976). In addition, social contact, received emotional support, and anticipated support are interrelated. Increased social contact is associated with increased emotional support and perceptions of support availability. Persons who have high levels of social support are thought to confront stressful or adverse conditions more successfully than do those who lack social support. Conversely, those who have inadequate levels of social support may be at risk of experiencing deleterious consequences for their own mental and physical health.

Mechanisms of Social Support

The protective effects of social support against stressful occurrences are thought to arise from several mechanisms, one being the encouragement (e.g., kind words from a close confidant) that one may receive when faced with adverse circumstances. The other is the availability of material aid and resources for dealing with challenges or adversity. For example, when one is confronted with the need to move to a new house, the availability of many friends to help with the move is indeed reassuring. Thus, social support enhances the individual's ability to cope with changes and crises, which are inevitable in life (Cobb, 1976).

Social Support Versus Social Network Ties

A distinction exists between supportive relationships and the total number of social ties that the individual has. Social support denotes perceived emotional support that one

receives from, or the value that one attributes to, social relationships. In contrast, the term *social network ties* is a more quantitative concept that embraces the number, structure, or pattern of ties that one has with other people or organizations. The mere existence of social ties is neither a necessary nor a sufficient condition for social support, nor is the absolute number of ties strongly correlated with social support. In fact, some types of social ties may be intrusive, stressful, or, at best, perfunctory. Close friendships and relationships with partners, spouses, or family members that are perceived as valuable or helpful engender social support. Social relationships, including those with family members and significant others, may be at best a mixed blessing: Many of the stresses that we experience evolve from our interactions with others. These stresses may arise from interactions with our very own family members, who may experience different intensities and outcomes of stress. Research has demonstrated the differential effects of spousal ties on men and women, the former being more likely to receive positive, protective effects from the marital relationship.

The Buffering Model of Social Support

The term *buffering* (sometimes called *moderating*) suggests that the impacts of noxious stimuli or stresses are attenuated by the availability of social support; absence of support, according to the buffering hypothesis, is linked to experiencing of the full consequences of stressful situations (Cobb, 1976; Kaplan, Cassel, & Gore, 1977; LaRocco, House, & French, 1980). The stress-buffering effect is more likely to occur when the social network is perceived as ready to provide assistance. The buffering model has also been extended to social network ties by specifying that they may lessen the adverse psychological consequences of stress (Friis & Nanjundappa, 1989). The buffering role of social support is attractive to practitioners, who view social relationships as more amenable to change than are the conditions in which adversity arises. Theorists posit that social support buffers some stressors more effectively than others, depending on the nature of the stressor. For example, a person who experiences a socially acceptable stress (such as personal illness) may be more likely to seek assistance from social support resources than would one who is confronted with a less socially acceptable stress, such as substance abuse (Mitchell, Billings, & Moos, 1982).

Sources of Social Support

Variations in the effects of support are believed to be related to the source of support; these effects may be conditioned by marital status, age, and gender. For example, support from spouses or friends may be more important than support from other network ties. Marital status, found to be salient in the social support process, causes married older adults to have more contact with family members than with friends and to receive more emotional support than unmarried older adults receive. An apparent paradox arises when comparing gender differences in social support. Some data suggest that women, in comparison to men, give and receive more support yet tend to have higher rates of psychological distress (Fuhrer, Stansfield, Chemali, & Shipley, 1999).

Social Support and Health-Related Outcomes

Investigators have examined the association among stress, social support, and mental and physical health outcomes, the latter including complications of pregnancy, all-cause mortality, chronic disease, and immune status. For example, isolated elderly persons who live in the community may be at higher risk of mortality than those who maintain social engagement. As a second example, immune status as a function of social support was studied among the spouses (assumed to be experiencing severe, chronic life stresses) of cancer patients; in comparison to those with low levels of support, spouses with higher levels of social support had better indexes of immune function.

Social Support and Mental Disorders

Much research has addressed the role of stressors and social support in the etiology of mental disorders. Noting that individuals vary considerably in their vulnerabilities to stressors, some authorities believe that social support may help to explain why some individuals who face high levels of stress do not develop psychiatric disorders (Lin & Dean, 1984). Absence of social support may be linked to psychiatric symptoms, especially depressive symptoms. Studies of patients who were suffering from depression reported that they had significantly less social support than did control patients. Not only do some researchers believe that the presence of social support plays a crucial role in the positive functioning of psychiatric patients, but lack of social support has also been associated with rehospitalization for depression.

SOCIALIZATION

Agents and Theories of Socialization

Socialization is the process of becoming a social being. During this process, individuals acquire ways of learning, thinking, acting, and feeling that enable them to familiarize themselves with the culture and participate in the social process. The main agents of socialization typically include family, peers, schools, media, and religion. Although the socialization process is most evident during childhood and adolescence, it covers the entire course of the life span. Erikson's eight stages illustrate the enduring process of socialization. The term *resocialization* emphasizes socialization as a process that never ends. A clear example of resocialization is what happens when someone joins a branch of the armed services. The uniforms, the regulations, and the regimen require the new recruit to learn new behaviors and attitudes appropriate to the new role.

There are at least two commonly used approaches to the study of socialization. The first approach emphasizes the individual and the development of the individual in the context of the culture and society. Studies from the field of psychology focus on topics such as stages involved in cognitive development, life course stages, and personality development. The second approach is a social perspective that emphasizes the development of the social self and the process of social and cultural transmission between generations. This is the major focus of socialization research among sociologists and cultural anthropologists.

With regard to cognitive development, the work of Piaget is especially important. Piaget identified four stages of cognitive development: sensorimotor, preoperational, concrete operational, and formal operational. Important at each stage is one's functioning in relation to the environment. This is accomplished in two ways: assimilation that involves modifying the environment in order to fit with an existing cognitive scheme and accommodation that entails modifying oneself in response to environmental demands.

An expected outcome of child and adolescent socialization is moral development. Freud's psychoanalytic theory emphasizes the affective component of morality. Children are viewed as motivated to act in accordance with their ethical principles in order to experience positive affects such as pride and to avoid negative moral emotions such as guilt and shame. Cognitive-developmental theory emphasizes the cognitive aspects of moral reasoning: the way the individual conceptualizes right and wrong and makes decisions about how to behave. For Piaget, the moral judgment of young children is characterized by an emphasis on abiding by the rules. The moral judgment of the older child, however, is characterized by the individual's viewing rules as arbitrary agreements that can be challenged. According to Piaget, moving from an authoritarian moral code to one based more on autonomy requires both cognitive maturation and social experience. For Kohlberg, moral judgment is the most important factor in moral behavior. Other factors that are necessary for moral judgment to become moral action include the situation and its pressures, motives and emotions, and a general sense of will or purpose. Kohlberg contended that a moral choice involves choosing between two or more universal values as they conflict (e.g., concerns of affection and truth).

The approaches to development of the social self are represented by Cooley and Mead. Cooley's concept of the looking-glass self suggests the importance of others in the development of one's self. The individual imagines how his behavior appears to others and, based on his perceptions of others' judgments, the self develops. According to Mead, the idea of the self emerges as one acquires language and interacts with others. The self is a gift to the individual from society.

Recent Issues

A number of issues widely discussed in the literature in recent years include peer groups, feminist perspectives, inadequate socialization, gender role socialization, and multigroup diversity. The significance of peer groups in the socialization process has been widely studied since the 1950s but has recently begun to gain more attention. Peer groups are increasingly important as the family system has been subjected to significant changes that include single-parent child rearing, stepparent socialization, multiple-parent siblings, and fragmentation of family roles and responsibilities.

Harlow's studies reported that peer groups could contribute to the socialization process of baby rhesus monkeys without a mother. Even in the concentration camps of Germany during World War II, groups of adolescents helped each other, and many children are believed to have survived as a result of such peer bonding. Similarly, countries as diverse as Brazil, Kenya, and Egypt have adolescents living

with other adolescents in groups in order to survive. The significance of siblings and peer groups in the caring and socialization of children in Cameroon and India, for example, has also drawn attention to the contribution of peer groups in the socialization process among comparative researchers.

The contribution of feminist perspectives has resulted in a shift in the emphasis directed to socialization, especially since the contributions of Chodorow and Gilligan. Chodorow utilized a psychoanalytic perspective to build on Freud's work and suggested that the sense of mothering in women was not biological, but rather a result of an ongoing relationship between mother and child. Gilligan's perspective on morality is marked by its recognition that men and women do not have identical patterns of moral development. She is critical of the major approaches of Piaget, Erikson, and Kohlberg because their findings may apply only to men and thus disadvantage women. Her research shows that concerns about both justice and care are represented in moral dilemmas, but males are more likely to have an abstract justice focus, and women are more likely to have a care focus due to the differential socialization process undergone by men and women.

Inadequate socialization is an explanation sometimes given for deviant behavior. Deviant subcultures provide a means for individuals to establish identity, even if it is a negative identity. Recent tragic events like school shootings in various areas throughout the United States are often explained, at least in part, by alluding to a failure in socialization. The media, with their emphasis on violent acts, are also targeted. It is important, however, not to mistake correlation for causation. Many other variables are involved in attempting to understand these recent violent events.

During the early stages of socialization, the child develops an awareness of himself or herself as male or female. Sex-appropriate behavior is emphasized whenever it is transgressed. In peer groups, nontraditional behavior is apt to be punished. This is especially the case for boys. Children will be rewarded, then, when they act in a way that is consistent and appropriate for their sex. More recently, sexual orientations other than heterosexuality are being more openly pursued, including bisexuality and homosexuality.

Although social class and ethnic distinctions in socialization have not been neglected in the past, multicultural perspectives in socialization are gaining attention. Multicultural perspectives include issues of class, race, language, and other ethnic viewpoints. The goals of socialization and the process of socialization vary significantly by social class, race, and ethnicity. For example, the exercise of discipline, values, attitudes, and belief systems may vary from group to group within the same culture.

In addition, topics within areas of socialization, such as child development, adolescence, and family socialization studies, have become specialties in their own right, and thus many more topics such as processes of learning, deviance, and emotions are being addressed in the context of socialization.

SOCIETY FOR RESEARCH IN CHILD DEVELOPMENT

The Society for Research in Child Development (SRCD) was established in 1933 as a professional organization to promote research on child development. The goal of the SRCD is to advocate for research in all relevant disciplines, including research that crosses disciplinary lines and research that is basic as well as applied. Currently, there are over 5,500 members who come primarily from psychology and human development disciplines but also from fields such as anthropology, history, sociology, biology, and neuroscience and professions such as pediatrics, child psychiatry, nursing, education, public health, and law.

Membership in the SRCD is open to individuals actively engaged in research or in teaching child or human development or those involved in the application of knowledge through advocacy, policy, or practice. Student memberships are available to postdoctoral, graduate, and undergraduate students as well. The organization and its members seek to promote the exchange of information across relevant disciplines as well as the application of research findings.

The SRCD was the outcome of the Committee on Child Development established by the National Research Council, the research arm of the National Academy of Sciences, in 1922. The goal was to find ways to promote research on children and families, which was generally lacking in American society at the time. The well-known experimental psychologist Robert S. Woodworth served as chair. During its years, the committee effectively fostered interest in the field by awarding fellowships, initiating conferences, and promoting publications. *Child Development Abstracts and Bibliography* (*CDAB*) actually began in 1927 as the first journal devoted entirely to child development issues. In 1933, at the recommendation of the committee, the SRCD was formed. Initially, there were approximately 400 members.

During the 70 years since its founding, the SRCD has become the major professional organization promoting research and application of research for children and families. Currently, its executive offices in Ann Arbor employ nine staff members, and its Office for Policy and Communications, located in Washington, DC, has two staff members. There are several standing committees in addition to the Society's Governing Council and Publications Committees. These include the Committee on Ethnic and Racial Issues, the Ethical Conduct Committee, the International Affairs Committee, the History of Child Development Committee, and the Policy and Communication Committee.

Publications

Publication of *Child Development* and the *Monographs of the Society for Research in Child Development,* as well as the *Social Policy Reports* and the Society's Newsletter, *SRCD Developments,* is a major part of the SRCD's endeavors. *CDAB* ceased publication in 2002 because there now are numerous online bibliographic sources and search systems that essentially cover the former journal's content. However, *Child Development* and *Monographs* continue to be among the most cited and most highly circulated of the many journals in the field. The *Social Policy Reports,* first published in 1984, provide summaries and commentaries of key issues and policies relevant to children and families. Analyses of current and pending legislation are often included as well. These are published three to four times a year and are available online.

Biennial Meetings

The SRCD holds its research meetings biennially, in the spring of odd-numbered years. Attendance typically exceeds 5,000 registrants, and the program, which runs for three and a half days, contains almost 3,000 presentations, including invited addresses, symposia, discussion hours, and poster presentations. The content is truly interdisciplinary and deals with many aspects of policy and application as well as theory-driven research.

Policy and Communications

The Office of Policy and Communications, in Washington, DC, deals with many issues, including acting as liaison with federal funding agencies and congressional committees, as well as various outlets for communications. One of its primary activities is the administration and supervision of the Science Fellows Program. Supported externally, there are two types of fellows, congressional and federal office. Each year, five to eight fellows serve the SRCD and learn about the operation of offices to which they are assigned while playing important staff roles as well. More than 100 fellows have gone on to important positions in local, state, and federal government as well as in the nonprofit sector.

International Presence

An important aspect of the SRCD that has grown rapidly in recent years is its involvement in international activities. This is reflected in the fact that it now has over 800 members from countries outside the United States, representing over 50 countries. Reports of research by scholars from other countries and studies conducted in other countries are appearing with increasing frequency both in the SRCD's journals and at its biennial meetings. Additionally, the SRCD's commitment to the use of research in public and social policy has expanded to consideration of the translation of research to policy in other parts of the world. It is becoming increasingly apparent that all societies and nations are concerned with the health and well-being of their children and families.

In its 70 years, the SRCD has established itself as a major influence in promoting quality research, obtaining resources to facilitate research further, communicating the knowledge gained, and promoting the application of findings to policy and practice.

SODIUM-POTASSIUM PUMP

Three families of membrane proteins hydrolyze ATP to obtain the energy needed for the transport of ions against their electrochemical gradients: V-type ATPases (e.g., transporters of hydrogen ions into lysosomal vacuoles and synaptic vesicles), F-type ATPases (e.g., the ATP synthase of the mitochondrial inner membrane), and P-type ATPases (which share a common asp~P reactive site and include the calcium ATPase of the cell membranes and the sarcoplasmic reticulum, the H-K ATPase of the stomach and elsewhere, and the sodium-potassium ATPase found on almost

every animal cell membrane). The sodium-potassium ATPase (Na-K ATPase) pumps sodium out of the cell in exchange for potassium. This process consumes a quarter of the basal metabolic rate and has profound consequences on the cell volume, ionic composition, and membrane potential, as well as on fluid transport across epithelial surfaces (DeWeer, 1985).

Functional Properties of the Sodium-Potassium Pump

The sodium-potassium pump is perfectly reversible—capable of consuming ATP to pump sodium out, and potassium into, the cell, as well as generating ATP by the reverse exchange of potassium for sodium. The function of the pump molecule is determined solely by the concentration of extracellular potassium and intracellular sodium, ADP and ATP; under physiological conditions, the cycle always consumes ATP to remove sodium from the cell.

Maintenance of Cell Volume

The Na-K ATPase is a powerful tool for countering the tendency of extracellular water to enter the cell, driven by the oncotic pressure of cell proteins. One immediate consequence of pump activity is that potassium becomes concentrated within the cell. Because cells are relatively permeable to potassium, chemical forces will tend to favor the loss of this extra potassium from the cell (cells are relatively impermeable to sodium at rest, so there will be little movement of that ion). Efflux of potassium, an osmotically active cation, will obligate the movement of chloride, a permeable anion, out of the cell to preserve electroneutrality. Because osmotic forces move water and potassium (or chloride) at a ratio of approximately 500:1, the Na-K ATPase is a particularly efficient water pump (Dwyer, 1998).

Establishment of a Membrane Potential

As the Na-K ATPase continues to operate, potassium will accumulate, and cell chloride will deplete, each establishing concentration gradients across the cell membrane. Consequently, diffusion potentials develop that are electrically negative for both ions. When steady state is reached, the electrical forces on the cell's permeable ions just counter their chemical gradients, and the resting cell membrane potential is established (Hille, 1992).

Transport of Fluid across Epithelial Surfaces

The existence of a sodium gradient allows the cell to use other transport proteins to move a wide variety of solutes, nutrients, and waste products into and out of the cell in a process termed *secondary transport.* Both electrical forces (the negative resting membrane potential) and chemical forces (the sodium concentration gradient) provide energy to couple the uphill transport of one or more molecules to the energetically favorable movement of sodium. Thus it is possible to absorb large quantities of fluid from the intestinal lumen by the cotransport of sodium and sugars or amino acids into epithelial cells lining the small intestine. Although most epithelia locate the Na-K ATPase on the basolateral aspect, neuroepithelia such as the choroid plexus and pigmented epithelia of the retina place the Na-K ATPase on the apical surface in order to better regulate potassium and bicarbonate concentrations in the brain (Rizzolo, 1999).

Electrogenic Property of the Na-K ATPase

Three sodium ions move out of the cell for every two potassium transported into the cell, generating a small electrical current. When the ratio of membrane surface area to cell volume is high, such as in nerve processes, the pump current is sufficient to hyperpolarize the membrane by up to 11 millivolts, potentially altering the electrical excitability of the nerve (DeWeer, 1985).

Metabolic Control of Pump Activity

The pump rate depends on intracellular sodium and extracellular potassium, with half-maximal stimulation at 10 to 20 mM sodium and 1.5 to 2.5 mM potassium. Minute-to-minute control of pump activity is modulated by a variety of protein kinases and phosphatases, with the identity of the Na-K ATPase subunit and the kinase or phosphatase determining whether the final result is stimulatory or inhibitory. Dopamine, for instance, inhibits the pump by an indirect cAMP-mediated inhibition of protein phosphatase 1. In the long term, pump activity is controlled by changing the number or type of the Na-K ATPase subunit present in the cell membrane (Blanco & Mercer, 1998).

Structure of the Sodium-Potassium Pump

The Na-K ATPase is a heterotrimeric protein integral to the cell membrane. The 112 kDa α-subunit contains the site where ATP is hydrolyzed, as well as the ouabain/digitalis inhibitory binding site, the sodium, and much of the potassium-binding site. The 40 to 60 kDa β-subunit shepherds the α-subunit to the cell surface, participates in the binding of potassium, and contains a very large, highly glycosylated extracellular domain that can act as an adhesion molecule, for instance, on glial cells. The 8 to 14 kDa γ-subunit is a hydrophobic polypeptide of uncertain function.

Various isoforms of both the α- and β-subunits are found in human cells, with the α_1- and β_1-subunits being the most common dimers. Identifiable nerve cells contain characteristic combinations of α_1-, α_2-, and/or α_3-subunits: for instance, in the eye, amacrine cells express α_2-subunits, bipolar cells express α_3, horizontal cells express α_1 and α_3, and ganglia cells express all three α isoforms. Glial cells can express α_2 or α_3 isoforms. The functional consequence of the highly specific tissue distribution of a multiplicity of sub-

unit combinations may lie in differences in kinetic or thermodynamic parameters of the specific heterotrimers or in a differential sensitivity to metabolic control (Blanco & Mercer, 1998).

SOMATOPSYCHICS

Definition

The term *somatopsychics* is derived from the Greek terms *soma,* meaning body, and *psyche,* which has become an English term as well. Somatopsychics refers to psychological effects engendered by somatic conditions. Such psychological states range from normal, to mild mood alterations (like irritability due to low blood sugar), to major psychiatric conditions.

Somatopsychics needs to be contrasted with psychosomatics. Psychosomatic mechanisms operate when psychological conditions produce physical symptoms, such as dry mouth and nervous sweating as a result of stress. The distinction between psychosomatic and somatopsychic is clear in most cases and in theory, but in reality, when phenomena of both kinds become intertwined and feed on each other, causes and effects are difficult to disentangle. When somatic and psychological causes successively bring about effects that begin to serve as the cause for the next level of effects, an etiological spiral evolves, making it difficult to identify the degrees to which psychosomatic or somatopsychic factors contributed to the final outcome. For example, stress leads to tachycardia (psychosomatic effect), which in turn causes uneasiness and anxiety (somatopsychic outcome), resulting in a headache (psychosomatic effect), which may trigger irritability (somatopsychic effect).

Neither the concept nor the term is new, but not all researchers are using the term *somatopsychics* correctly, which has created some confusion. Many have used the popular term *psychosomatic* in lieu of somatopsychic when referring to a body-mind connection, regardless of the direction in which the cause and effect arrow points.

Linguistics attests to the recognition of somatopsychic connections. For example, the thymus gland, considered to be the seat of emotions, was named after the Greek word for mood, *thymos,* while hysteria, formerly believed to be related to the uterus, was labeled after the Greek term for uterus, *hyster.*

History

Somatopsychic connections were understood by Hippocrates, Aristotle, and Galen. In the 1700s Lammetrie's "L'homme machine" functioned on a somatopsychic basis. Cabanis perceived the mind as a function of the brain. Gall's phrenology led to Lombroso's somatically based theory about the criminal mind. Fechner's theory of psychophysical parallelism asserted that every physical event has a psychological correlate and vice versa. Lotze, Ribot, and Galton prominently emphasized the somatic basis of psychological processes. Among prominent promoters of somatic hypotheses of mental illness, in the second half of the 19th and at the beginning of the 20th century, were Broca (localization of brain functions), Taine (nerve reflexes), Müller, Weber, Wundt, Jakobi, Griesinger, Westphal, Meynert, Kraepelin, Bleuler, and Wernicke, who used the specific term *somatopsychic.* Meynert, for example, not only argued for an etiology of mental illness rooted in brain pathology but also supported it with specific observations concerning destruction of fibers, blood flow to the brain, and so on. Kretschmer connected body build and personality and proposed a corresponding affinity toward a specific mental illness. Sheldon's body based theories about temperament followed. Around 1900 Pavlov established scientific proof for four personality types based on distinguishable patterns of nervous system reactivity.

In 1913/1973 Karl Jaspers presented several etiologies of mental illness, among them the somatopsychic etiology, which is divided into three parts: (1) brain pathology (trauma, tumors, infection, vascular system–related pathology, genetic deficits, deterioration due to aging, etc.), (2) physical illness producing symptomatic psychoses (infectious diseases, endocrine disorders, uremia, etc.), and (3) effects of toxic substances (morphine, cocaine, carbon monoxide, alcohol, etc.).

With the rapid expansion of biomedical research in the twentieth century, evidence for a somatic basis of many psychological disturbances mounted and in the 1970s lent credence to orthomolecular psychiatry. The theories of Pauling, Kety, Rimland, Pfeiffer, Osmond, and others identified specific mental disorders as somatopsychic effects of biological etiology. They countered adverse genetic, biochemical, nutritional, and environmental conditions with megavitamin and/or mineral therapy to treat and prevent mental illness.

Richard C. W. Hall's landmark 1980 book brought the

concept of somatopsychics into focus. With his colleagues he documented and cataloged psychological presentations of physical illness as well as psychological side effects of pharmacological agents. Additional somatopsychic outcomes were reported to be related to genetic factors, to normal physical changes such as hormonally induced biorhythms or life phase changes, as well as to toxic substances, including gases, and to ambient environmental conditions.

Research into the somatic etiology of mental disorders is growing rapidly, forecasting a more accurate understanding of mental illness and leading to a new, largely somatopsychically based systematization and to new codification of mental illness.

Somatopsychics of Everyday Life

Everyday life is full of experiences illustrating etiology and effects of somatopsychic mechanisms. Parents are familiar with the mood changes that occur in children when they are hot, tired, or hungry. But people of all ages get irritable because of low blood sugar, heat, and fatigue. Effects of sensory overload, such as noise or heat, and many forms of sensory extremes, including sensory deprivation, are reflected in psychological sequelae. Total sensory deprivation as used in some prisons can lead to psychotic states and hallucinations. On the other hand, enjoyable sensations trigger psychological effects as well. Scents can evoke pleasant feelings that may include seductive messages. Music can be stimulating or calming, depending on tone, volume, and rhythm.

Diminished alertness and reactivity are well documented in fatigued drivers of motor vehicles. Fatigue is a generally recognized factor in diminished capacity to function mentally, particularly in learning. In fact, one of the earliest psychological tests was developed by Ebbinghaus (1897) to study fatigue in school children. Limitations of reasoning ability are easily accepted as an effect of a not-yet matured brain in young children but cause concern when they are the result of a deteriorating brain in an aging person.

Hormones are known to cause emotional changes in adolescence and in pregnancy and menopause and are related to mood swings in premenstrual syndrome. Postpartum depression is attributed to the birth-related sudden disruption of the hormone levels accompanying pregnancy.

Somatopsychic effects of common-use substances are well recognized: the stimulating effects of caffeine and nicotine, as well as the initially relaxing but later depressing and judgment-impairing effects of alcohol. Many toxic substances have more than a somatic impact. Lawsuits alleging lead poisoning cite outcomes of learning disabilities, lethargy, and so forth. Carbon monoxide exposure (car exhaust, cooking gas) can lead to memory deficits, apathy, and depression. Brain trauma due to insults from various causes like forceps birth, domestic abuse, accidents, or brain surgery may result in mental deficiencies, adverse emotional reactions, and personality changes. In rare cases trauma has caused a state of euphoria.

Sports-related somatopsychic phenomena include the runner's high, attributed to endorphins, and the SCUBA divers' rapture of the deep, a state of nitrogen narcosis that expresses itself in a euphoric, drunk-like state accompanied by cognitive impairment and poor judgment. High altitude exposure affects mountain climbers and skiers along with inactive sightseers. Apart from physical distress it may cause irritability, impaired judgment, and in extreme cases panic attacks, delirium, and hallucinations.

Light availability affects mood. Diminished presence of daylight in the northern and southern regions, as in Alaska and Scandinavia, causes depression in many people. *Wetterfühligkeit,* more readily acknowledged in Europe, refers to weather sensitivity. It implies that a person's vascular system is affected by weather conditions, particularly changes in barometric pressure affecting the emotional state. The Föhn, the oppressive, warm alpine winds, are blamed for migraine headaches as well as for bringing on depression and even suicide in susceptible individuals.

Disruption of circadian rhythm, especially when resulting in sleep deprivation, reduces optimal physical and mental performance and also appears to play a major role in depression. Leading causes are jet lag and shift work, particularly when shift cycles alternate as soon as the body has begun to adjust.

Medical Illness Producing Psychological/Psychiatric Symptoms

The American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition recognizes the existence of somatopsychic conditions as long as a general medical condition or a specific substance caused the mental disorder, but it does not explicitly label the mechanism involved as somatopsychic. Such recognized medical conditions likely to generate psychological or psychiatric effects include brain tumors, head trauma, neoplasms, neurological, endocrine, and cardiovascular conditions, specific infections, autoimmune disorders, hepatic and renal disease, and fluid or electrolyte imbalance. Several researchers have pointed out that side effects of medical illness or substance impact may lead to a misdiagnosis of mental illness, which most likely preempts the needed treatment of the underlying condition. Missed early interventions due to missed diagnoses can endanger the patients' life, as in brain tumors. Misleading symptoms depending on tumor site can include personality, affective and cognitive changes, altered perceptions, anxiety and depression, tactile or visual hallucinations, and depression.

Selected Examples of Somatopsychic Effects

Substance-Related Somatopsychics

Somatopsychic effects may be related to a substance of abuse or to withdrawal from it. They also occur when a person incurs a deficit or accumulates a toxic amount of a

needed substance, such as a vitamin or mineral. Psychotic, mood, and anxiety disorders, for instance, may be associated with intoxication with and/or withdrawal from many substances. Phencyclidine (PCP), for example, causes a sense of emotional numbing, detachment and isolation, and change in body and spatial images. If it triggers a psychotic episode, the symptoms may be indistinguishable from those of schizophrenia.

Common-use substances like alcohol, caffeine, and nicotine have their somatopsychic effects: Caffeine increases energy and alertness and acts as a mood elevator, but anxiety, fatigue, and depression are bound to follow at abstinence. Somatopsychic effects of alcohol consumption vary, ranging from elevated mood, impaired judgment, anger, rage, and violence to fatigue, or may lead to dysphoria and depression. Memory deficits are common after heavy drinking. Excessive, long-term use can lead to amnestic disorder, dementia, and delirium. Nicotine use increases arousal, vigilance, and concentration and reduces stress and irritability. Severe irritability follows withdrawal.

Malnutrition alters emotional reactivity and cognitive efficacy (starvation, poverty, dieting). Somatopsychic effects due to nutritional deficiencies, though present in the general population, have been noted prominently in the elderly due to both insufficient intake and diminished absorption capacity. Incorrect diagnoses of organic brain syndrome, paranoia, or depression have been made in patients suffering from nutritional deficits. Vitamin and mineral deficiencies can lead to irritability, confusion, mental deterioration, dementia, delusions, disorientation, apathy, hallucinations, depression, anxiety, and so on. Accumulation of toxic amounts of vitamins and minerals can generate similar outcomes. Toxic levels of copper may even mimic psychosis indistinguishable from bipolar disorder or schizophrenia.

Somatopsychics of Mental Disorders and Other Psychological Conditions

Some mental conditions are exclusively of somatic etiology. Most types of mental retardation and autism fit this category. Not as clear-cut are the etiologies of schizophrenia, mood, and anxiety disorders. These disorders, depending on type and severity, are believed to arise from psychogenic and/or somatogenic conditions. Stress can interact with genetic predisposition. In addition, psychological factors can precipitate a psychosomatic outcome. Depending on the resulting somatic condition, it may become the somatic basis for a mental disorder. A selection of recognized etiologies follows. The samples provided are not intended to be all-inclusive.

1. *Mental retardation.* Most cases of mental retardation are somatically based.
   a. Mental retardation related to the *prenatal* period includes chromosomal disorders, inborn errors of metabolism, disorders of the urea cycle, developmental disorders of brain formation such as hydro- and microcephalus, maternal malnutrition, and substance abuse or illness (measles, diabetes).
   b. *Perinatal* phase. A healthy fetus can develop into a child with mental retardation due to unfavorable birth-related events, such as maternal sepsis, and birth delays, umbilical cord accidents, head trauma, and so on. Other etiologies are neonatal disorders, such as infections or intracranial hemorrhage.
   c. Severe malnutrition in the *postnatal* phase is a leading cause of mental retardation. Other damaging factors are head injuries, lead and mercury poisoning, aspirin-related Reye syndrome, childhood onset of metabolic disorders, infections, postimmunization disorders, parasitic infestations such as malaria, seizure disorders, and so on.
2. *Autism.* This has been related to bilateral brain damage in early life, genetic roots, neurochemical and immunological factors, deficient oxygen delivery to the brain, in utero insults, and so forth.
3. *Schizophrenia.* While the evidence for somatic etiologies of SCH is increasing, no singular somatic cause of schizophrenia has been identified. The following are some of the more widely recognized somatopsychic etiologies of SCH. They center on (1) genetic factors; (2) environmental factors, including maternal malnutrition and effects of infectious agents or antibodies operating prenatally; (3) lipid dysfunction; (4) abnormal brain lateralization and/or abnormal hemispheric communications, brain damage occurring as a result of abnormal prenatal brain development, head injury, hypoxia, and so forth; (5) neurodevelopmental errors and neurological malfunction; (6) extreme prematurity at birth; and (7) biochemical deficiencies or imbalances. The broad variety of etiologies producing schizophrenic symptoms calls for a new, somatopsychically based understanding of the disorder.
4. *Depression.* While there is psychogenic depression in response to negative life events, depression also has undisputed somatopsychic etiologies. They include genetics, biorhythms (circadian rhythms, sleep length, and quality), and environmental (sunlight deprivation) and biochemical factors, like activity of monoaminergic neurons, norepinephrine, serotonin- and thyrotropin-releasing hormones (TRH), dopamine deficiency, reuptake of norepinephrine, serotonin and dopamine, and others. In women, hormone-related depression has been associated with premenstrual syndrome, pregnancy, the postpartum period, and menopause.
5. *Mania.* In addition to genetics, mania has been related to various somatic etiologies, such as excess epinephrine and serotonin production, cerebral trauma, left hemisphere injury, sleep disruption, and CD4 count in HIV-infected patients.

6. *Anxiety.*
   a. Research has found that a single dominant gene causes a predisposition to panic disorder. A panic experience can be triggered when the autonomic nervous system is activated by agents like caffeine, yohimbine, lactic acid, increased CO inhalation, and so on. One hypothesis theorizes that patients with panic disorder may chronically be in a higher state of arousal.
   b. Obsessive compulsive disorder is classified as an anxiety disorder, and its somatopsychic etiology is increasingly recognized. Among such etiologies are genetics, abnormal brain structures, and a dysfunction of the serotonergic system.

Outlook

The rapidly expanding body of scientific findings has broadened knowledge about the role of somatic factors in the etiology of psychological and psychiatric presentations. Unless a condition is strictly psychogenic, symptoms are less significant in defining a disorder than their somatic origin is. Identical symptoms of psychopathology can result from vastly different somatic etiology. Somatopsychic research calls for a reassessment of the historically evolved understanding of so-called mental illness, which needs to be redefined in biological-medical terms, accepting etiology as the defining category, no matter how serious the side effects of mental and emotional disturbance are. Many of the old categories, based on symptoms, cannot adequately accommodate disorders that are now understood etiologically and diagnosed with the help of innovative scientific methods and defined by new and different standards. Expected new terminology portraying mental illness largely as a side effect of somatic conditions can remove stigmatization of mental patients and will encourage them to seek timely treatment. More accurate diagnoses invite more precisely targeted interventions, which will improve the efficacy of treatment.

SOMATOSENSORY FUNCTION

Somatosensory function is the ability to interpret bodily sensation. Sensation takes a number of forms, including touch, pressure, vibration, temperature, itch, tickle, and pain. The somatosensory system allows individuals to interpret sensory messages received from the body and consists of sensory receptors located in the skin, tissues, and joints; the nerve cell tracts in the body and spinal cord; and brain centers that process incoming sensory information (Figure 1).

Sensory information is first detected in at least six specialized sense organs in the skin, categorized by rapid or slow response characteristics. Rapid responses occur in hair-follicle receptors, which detect hair movement in hair-covered skin. Hairless skin contains receptors called Meissner's corpuscles that respond rapidly to sudden displacements of skin and low-frequency vibration of up to 80 cycles/s. Another rapid sense receptor, found in hairy and hairless skin, is the Pacinian corpuscle. Pacinian corpuscles respond to sudden skin displacements and to high-frequency vibration, sensing signals at 30 to 800 cycles/s. These rapid sense receptors detect movement across skin, as well as vibration and fast but subtle changes in pressure. Sense receptors with slower responses include Merkel's disks, responsive predominantly to skin indentation; Ruffini endings, which respond to skin stretch, and free nerve endings, which detect touch, pressure, pain, and thermal sensations. These slower receptors occur in both hairy and hairless skin. Free nerve endings are present also in arterial walls and joint surfaces. Various types of nerve endings in joints, tendons, and muscles provide input for kinesthesis, the knowledge of the position and movement of one's body parts. Visceral sensation comes largely from nerve endings in the muscles surrounding the viscera. The viscera themselves are fairly insensitive to touch, temperature, and pain.

The sensory receptors send their information to the spinal cord through peripheral afferent nerves in the arms, legs, body, and head. A total of 31 pairs of nerves (one member of each coming from either side of the body) enter the spinal cord from the body, and four so-called cranial nerves supply sensory information from the head, including structures such as the tongue and pharynx. As the nerves enter the spinal cord, they make connections, or synapses, within the cord tissue. The sensory information then travels to the brain via two major pathways.

The two pathways that convey sensory information from spinal cord to brain serve largely different functions. The dorsal column–lemniscal system transmits mainly touch and pressure information and consists of large and fast nerve fibers that transmit signals at rates of 30 to 110 m/s. The fast information flow enables sensations of movement

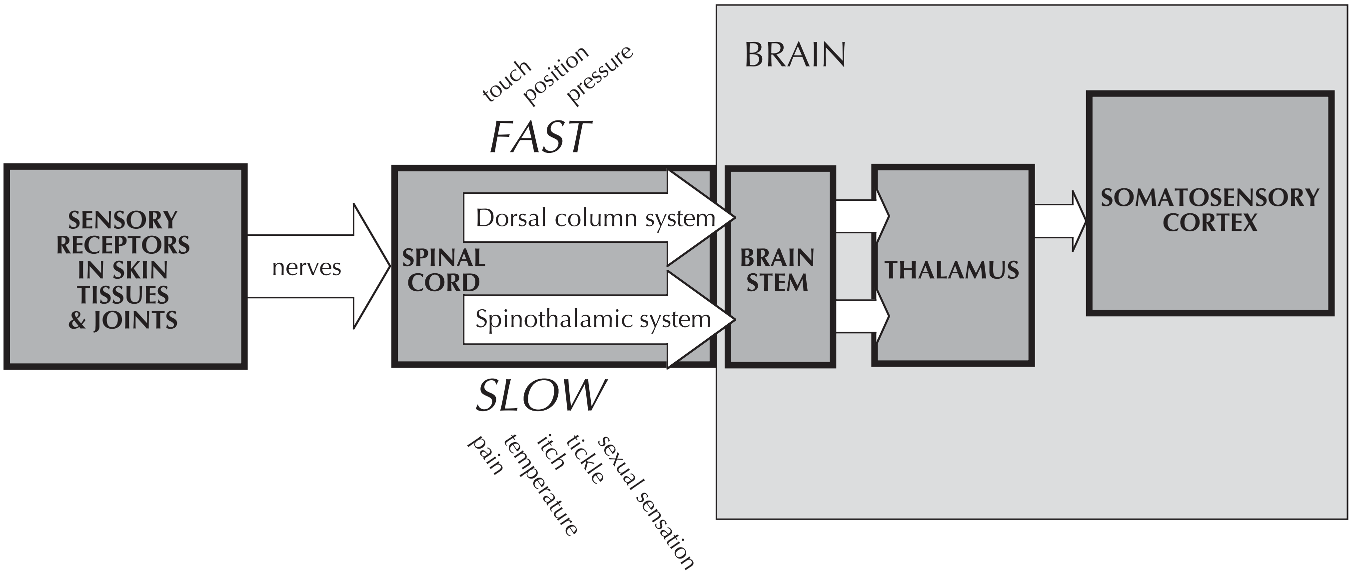

Figure 1. The somatosensory system and its components.

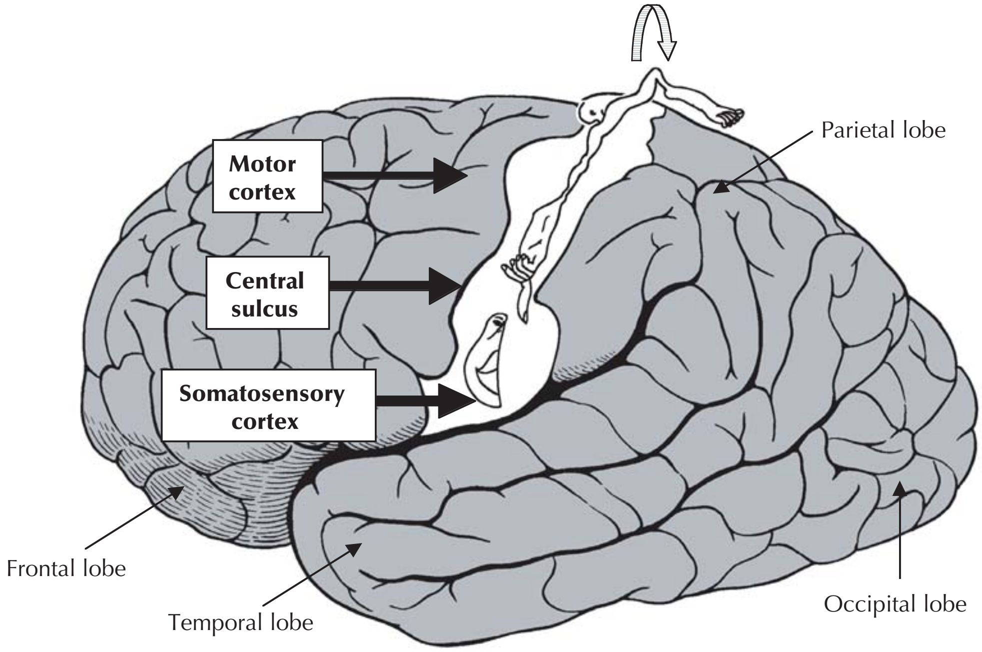

Figure 2. Human somatosensory cortex (white shading) is separated from motor cortex by the central sulcus. The spatial organization of bodily sensation shown as an homunculus, which continues along the inner surface of the brain's hemisphere (folding arrow).

across skin to be detected, as well as rapidly repetitive signals to be ultimately sensed as vibration. In addition, this pathway transmits information with high spatial resolution. Touch sensations are localized with a high degree of accuracy, and fine discriminations in intensity can be made. These processes are due to a key characteristic of this system: rapid adaptation, in which a response to a persistent stimulus dies away quickly.

The second system is the spinothalamic system. This slower, low-resolution pathway transmits mainly information relating to pain, temperature, tickle, itch, and sexual sensations. Typical signal transmission rates range from 8 to 40 m/s and are generally slow because information is sent down smaller nerves than in the dorsal column system. The ability to transmit rapid repetitive signals is poor; spatial resolution is fairly crude; and the spinothalamic system does not adapt quickly. This is important because a persistent sensation of hot, cold, or pain will stimulate the individual to remove the affected body part from a noxious and potentially damaging stimulus.

When fibers from the dorsal column and spinothalamic system enter the spinal cord, their connections are quite different. The dorsal column system fibers take two directions: the so-called lateral and medial branches. Fibers from the lateral branch make synapses in the spinal cord, which ultimately produce spinal cord reflexes and a pathway connecting the spinal cord and the brain's cerebellar hemispheres, structures that play a key role in motor control. Fibers from the medial branch travel to the brain stem to a structure called the medulla. Here the fibers decussate, or cross, from one side of the body to the other. From the medulla, tactile information flows through the medial lemniscus to the thalamus of the brain.

By contrast, in the spinothalamic system some fibers synapse and then decussate locally in the spinal cord. The spinothalamic system sends its information forward via two major routes. First, crossed fibers travel to two regions of the thalamus: one set goes to the same thalamic region as the dorsal column fibers, whereas the other travels to another part of the thalamus. Second, crossed and uncrossed fibers are sent to the reticular nuclei in the brain stem and the thalamus. These latter connections are important for the chronic pain perception. The increased arousal that these signals produce explains why it is difficult to sleep when one is in pain.

The thalamus is the brain's relay station for sensory input, including vision and hearing. From the thalamus, the tactile information travels to a brain region called somatosensory cortex (Figure 1). Somatosensory cortex is the primary brain region dealing with sensation. It lies in the parietal lobe (Figure 2), namely on a surface and fold of brain known as the postcentral gyrus and the central sulcus, respectively. The central sulcus separates the sensory cortex from the motor cortex.

Each side of the body's surface is mapped to somatosensory cortex of the contralateral, or opposite, side of the brain. Sensation in the pharynx, tongue, and teeth is located below that of the face and hands, which in turn are located in regions below those for the trunk and legs (Figure 2). Sensation in the feet and genitalia are located in the cortex that lies between the two hemispheres of the brain. (The arrangement of motor cortex follows a similar topo-

Figure 3. Brain activation study of hand somatosensory cortex elicited by brushing the fingers and palm using functional magnetic resonance imaging at 3 Tesla (graded bar displays correlation coefficient range for $p < 0.01$ level). The horizontal broken line on the brain (inset) indicates display plane for the activation image.

graphical organization. Hence, injuries to these brain regions can be localized from observed impairments in sensory and motor functions of various parts of the body.) The spatial map of somatosensory cortex is not a precise representation of the body. The hands, face, and lips take up a disproportionately large part of the map. These body parts typically are the most sensitive and supply the most information about a contacting stimulus relative to other body areas such as the back. The distorted somatosensory map of the body's surface is often known as the sensory homunculus (Figure 2). Noninvasive activation studies of somatosensory cortex in response to tactile stimulation of a particular body part, such as the hand (Figure 3), are now possible and are beginning to be used routinely in presurgical planning for tumor and epilepsy surgery.

The secondary somatosensory cortex, located slightly below and behind the primary somatosensory cortex in each hemisphere, also deals with sensory information. It receives its input from two thalamic regions predominantly via the spinothalamic system, in addition to receiving input from the primary somatosensory cortex.

The analysis of tactile information in the brain does not stop at somatosensory cortices. We can recognize objects when our eyes are closed by running our fingers over them or by moving them around in our hands. This is possible because the somatosensory (and also motor) cortices send information to other brain regions that perform these sophisticated functions.

SPATIAL MEMORY

Spatial memory is ubiquitous. Almost every action takes place in space and requires some form of spatial memory. In addition, spatial memory can be studied easily in animals, which often have outstanding spatial capabilities. Consider, for instance, the memory capabilities of food-storing birds. During autumn, many birds store seeds that they retrieve later on (often several months after the storing episode), when the environment does not provide the necessary amount of fresh food. Thus an individual bird will store hundreds of food items in numerous caches scattered throughout its home range. Retrieving these food caches will depend at least partly on the bird's memory for their locations. For example, laboratory experiments demonstrate that Clark's nutcrackers show excellent retention of many spatial locations over time periods greater than 9 months. Other observations suggest that scrub jays remember more than just spatial locations. They also remember what type of food has been cached and whether it is perishable.

Such capabilities are not unique to birds but are found in many rodents as well. For example, laboratory rats perform very well on the radial maze, a memory task in which they have to gather food at the end of the arms of a radial maze. As arms depleted of food are not rebaited, rats learn to avoid locations that have already been visited. They form a memory of depleted arms based on a representation of the food locations relative to the configuration of visual cues within the testing environment (Roitblat, 1987). Rats are also very proficient at the water maze navigation task, in which they must find a safe platform in a pool filled with water. As the start position is changed from trial to trial and the platform is not visible, the animal cannot apply rigid solutions to the problem. Instead, it must rely on the visual cues located outside the swimming pool so as to infer the platform location. Rats quickly learn to swim directly toward the platform, even when novel start points are used. Thus, they learn the platform location relative to the environment and are able to plan direct paths, whatever their current location. Other studies suggest that the rat's spatial memory encompasses the general structure of space. Such cognitive maps allow rats to use efficient novel paths when the circumstances require it; for example, they can make detours when previously available paths are blocked (Poucet, 1993).

Among the brain areas that support spatial memory, the hippocampus, a structure that lies below the cortex in mammals, has received much attention in recent years. Damage to the hippocampus induces dramatic and permanent deficits in spatial tasks. Rats with such lesions are impaired in the water maze navigation task and have an impaired spatial memory in the radial maze. Their spatial patterns of exploration are also strongly altered, and they fail to detect spatial changes in a familiar environment (see Poucet & Benhamou, 1997, for a review). However, critical evidence is provided by the existence of cells that carry a spatial signal. Such cells can be classified as place cells and head direction cells. Place cells are found in the hippocampus proper. A place cell fires rapidly when the rat is in a restricted portion of the environment independently of the animal's heading and is usually silent elsewhere (O'Keefe, 1976). Each place cell has its own specific firing location. Head direction cells are found primarily in the postsubiculum, an area closely related to the hippocampus. The firing pattern of head direction cells depends only on the heading of the animal and is independent of its location (Taube, 1998). Each head direction cell has its own specific preferred firing direction. Both head direction cells and place cells share many properties, including being under the control of visual and idiothetic (motor-related) inputs. Thus, the two types of cells have access to the same information and form a tightly connected functional neural network that provides the animal with information about both its location and its heading. Their cooperative function is hypothesized to allow the rat to navigate efficiently in its current environment.

Cells that carry somewhat similar spatial signals have been found in the hippocampus of nonhuman primates, suggesting a comparable function in higher species (Ono, Nakamura, Nishijo, & Eifuku, 1993). In addition, recent evidence based on functional neuroimaging of brain activity during navigation in familiar yet complex virtual-reality environments suggests that the human hippocampus also plays a special role in spatial navigation. Activation of the right hippocampus is strongly associated with spatial knowledge and navigation (Maguire et al., 1998). This finding bears a direct relation to animal studies and supports the hypothesis that the role of the hippocampus in spatial memory should be extended to other mammal species, including humans. Further work will be necessary, however, to understand how the hippocampus interacts with other structures (e.g., the parietal cortex) thought to be important for the representation of spatial information.

SPECIFIC HUNGERS

A specific hunger is an increased preference (or craving) for a specific food or flavor at a particular time, such as during conditions of vitamin deficiency. It is distinguished from a consistent preference for a particular food or flavor, such as the fact that some people like jalapeños and others do not. It is also distinguished from pica, which is a preference for eating something apparently useless or harmful, such as clay.

Specific hungers were first documented by Curt Richter (1943, 1947), who found that rats would adaptively modify their intake of carbohydrates, fats, proteins, sodium, calcium, the B vitamins, vitamin E, and others at various times. For example, adrenalectomized rats increase their intake of sodium chloride (NaCl) to compensate for the excessive salt they lose when they urinate. Parathyroidectomized rats increase their calcium intake, again in response to increased need. Pregnant and nursing rats increase their intake of proteins and calcium. Later researchers demonstrated that rats also increase their preference for high-protein diets after a period of protein deficiency (DiBattista & Holder, 1998).

The specific hunger for sodium chloride apparently depends on an innately programmed mechanism that can be triggered by sodium need. A rat that becomes deficient in NaCl immediately shows an enhanced preference for foods and liquids containing NaCl or containing the similar-tasting, but toxic, LiCl (Nachman, 1962; Richter, 1956). This preference depends on changes in the taste of the salt solution (Scott, 1992) and is greatly weakened after damage to the chorda tympani, the nerve responsible for taste from the anterior tongue (Frankmann, Sollars, & Bernstein, 1996). That is, salty substances taste better when the body needs them. Anecdotal evidence suggests that humans have similar mechanisms for sodium hunger (Wilkins &

Richter, 1940). Thus, the salt craving reported by athletes after extensive sweating or by women during heavy menstrual bleeding has a biological basis.

In contrast, other specific hungers develop by trial-and-error learning, largely by process of elimination (Rozin, 1967; Rozin & Kalat, 1971). For example, if a calcium- or thiamine-deficient rat is offered several foods, one of which contains the needed nutrient, it shows no immediate preference, but gradually learns an aversion to the deficient foods and thus an apparent preference for the food containing the nutrient. That is, what appears to be a preference or craving for one food is often an avoidance of the other choices. Similarly, rats on a diet deficient in certain amino acids learn an aversion to that diet and therefore prefer a new and potentially better diet (Wang, Cummings, & Gietzen, 1996). However, a rat on a deficient diet prefers an old, "safe" diet to both the deficient diet and any new, untested one.

Many specific hungers or cravings remain unexplained, however. For example, many people report a marked craving for chocolate at certain times. The chocolate craving is particularly common among women around the time of menstruation. One hypothesis has been that chocolate acts as a kind of tranquilizer or in some other way counteracts the discomfort of menstruation—and presumably discomfort at other times as well. However, providing either tranquilizers or hormonal treatments does not weaken the chocolate cravings of menstruating women (Michener, Rozin, Freeman, & Gale, 1999). It is possible that people learn a preference for chocolate because of some benefit and then maintain the habit even when it is not needed. However, the data currently available do not explain chocolate cravings.

A new kind of specific hunger has been observed that cannot be described as a taste craving. Some chimpanzees and possibly other primates occasionally chew and suck the bitter pith of the plant *Vernonina* or swallow whole leaves with rough edges without chewing them (Huffman, 2001; Lozano, 1998). From their facial expressions, they do not appear to enjoy the taste, and people who have tried the pith or leaves describe them as bitter and foul-tasting. The pith and leaf eating are common only during the rainy season, which is also the time of the greatest spread of the intestinal parasite *Oesophagostomumi,* a nematode. Chimpanzees that engage in pith and leaf eating usually appear to be in poor health, with diarrhea, lethargy, and weight loss. In at least a few documented cases, chimpanzees that ate pith or leaves showed improved health afterward, and there was a decrease in their number of intestinal parasites. Thus it would appear that chimpanzees have discovered the value of these plants as medications, as have, in fact, the indigenous humans of the same regions (Huffman, 2001). Some biologists, however, remain skeptical. First, none of the researchers has adequately documented that the leaves and bitter pith that chimpanzees sometimes eat have better parasite-killing properties than other available plants. Second and more important, it is difficult to imagine how chimpanzees could have learned the medicinal value of plants. Chimpanzees generally keep to a consistent diet and seldom try eating various plants at random. What is the chance that an ill chimpanzee would try eating a bitter-tasting wood, consume enough to do some good, and associate the recovery with the bad-tasting substance? Researchers vary in how plausible they consider this scenario, but we need not assume that each individual learns the behavior independently. If chimpanzees have indeed learned to self-medicate to combat parasites, they presumably rely heavily on social learning—that is, imitation of others that have already developed this behavior. Social learning of food preferences and aversions is well documented in several species, including rats (Galef, 1996), and it seems likely that chimpanzees would be highly adept at this kind of learning. Still, more field research and laboratory research will be needed to explore the possibility that chimpanzees have learned the medical value of certain plants.

SPEECH AND HEARING MEASURES

Clinical, industrial, forensic, and research purposes are among those served by speech and hearing measurement. The nature of the tests and procedures used depends on the purposes of the testing.

Speech-Language Measures

Speech Communication Systems

For purposes such as development of telephone fidelity, speech may be measured by experimental psychologists or engineers in terms of sound wave properties such as frequency, amplitude, and sound waveform. The amount of power given off by a speaker and the distribution of that power over time may also be measured. Researchers have devised graphical methods, which use mathematical Fourier analysis of the waveform, for analyzing speech into its component frequencies. Researchers also use electrical methods such as the sound spectrograph, which notes the changes in intensity-frequency pattern as a function of time. Visual patterns (spectrograms) may be obtained and compared for various words or phrases. The efficacy of speech communication systems may be measured by use of laboratory articulation testing methods. Forensic investigators and others may apply these patterns for voiceprints, which are unique to each individual. Speech and hearing scientists also use such methods in research.

Physiological Function

Physiological aspects of speech and voice production have been studied by such methods as electrophysiological and cinefluorographic methods. Studies of respiration may be tied to voice production, which requires a flow of air between the vocal bands. Computerized study of the variables of phonation (voice production) yields information that may be of both research and clinical use for determining deviant or disordered voice parameters. With ongoing development of technology, magnetic resonance imaging (MRI), functional magnetic resonance imaging (fMRI), positron emission tomography (PET scans), single photon emission computerized tomography (SPECT imaging), and computerized axial tomography (CAT, or CT, scans) may be used for studies of brain function of various aspects of both normally functioning and disordered speech and hearing activities. Such methods now permit observation of brain activity during specific tasks, rather than only conjecture and inference from aspects of overt behavior that previously could not be more centrally observed. In this way, researchers have been investigating ongoing aspects of listening, speaking, reading, writing, musical listening, singing, dyslexia, sign language usage, and other kindred language, speech, and hearing phenomena.

Language

Assessment of language disorders may include tests of various aspects of language function, such as grammar, syntax, pragmatics, sequencing, memory, word retrieval, and other subareas. These are viewed in relation to age, language environment, and other relevant information about the individual being tested. Numerous test instruments have been normed for various populations. These instruments can yield information about developmental level and potential development of disordered language when used by appropriately trained professionals for research or clinical purposes.

Both observational and experimental techniques for the measurement of various aspects of verbal context of speech and other areas of speech and language have been developed. Interdisciplinary approaches to child language have included consideration of sociological, psychological, physiological, linguistic, and other such variables.

Clinical Assessment of Speech-Language Function

Evaluation of speech-language function for clinical purposes entails assessment of one or more of a number of subareas of speech and language. These subareas may include auditory perception for speech and language function; articulation, or phonology (the production of speech sounds); voice, or phonation and resonance; language perception, processing, and production; and fluency (which includes stuttering). There are also instruments to evaluate pragmatics, or the appropriate use of speech and language in interactional context. Language and speech recall, memory, and sequencing functions, as well as phonological awareness of speech sounds (needed for reading and writing), may also be assessed.

Personnel qualified to administer clinical evaluations include certified speech-language pathologists and certified audiologists who have been awarded the Certificate of Clinical Competence (CCC) in speech-language or in audiology by the American Speech-Language-Hearing Association

(ASHA) based in Rockville, Maryland. State licensure may be alternate evidence of qualification. Audiologists have been developing additional certification criteria. When determining etiology and planning treatment of voice and hearing problems, referral for medical evaluation should always be considered in the assessment plan.

Although numerous standardized tests continue to be developed, because of the variability of multicultural and regional norms, speech-language evaluation frequently also includes informal assessment by qualified professionals to rule out misidentification of regional or bilingual patterns as being clinically diagnostic of disorders that are not there. Clinical assessment of bilingual speakers is a growing area of need that also requires the services of certified or licensed bilingual professionals.

Hearing Measurement

Measurement of hearing for research purposes has included study ranging from localization of sound in space to electrical responses from the central auditory system, in order to yield information that may be of both experimental and clinical interest.

Clinically, pure-tone audiometers generate vibrations that may be adjusted to vary the intensity (loudness) of tones ranging from low to high frequency (pitches). By indicating when each tone is heard, an individual may be assessed for the threshold of hearing throughout the audible range of frequencies. An audiogram is used to graph the results of the test. Hearing loss, in decibels, is recorded for frequencies tested. The type of hearing loss may then be determined by evaluating the data obtained from audiometric and other clinical tests. Middle-ear function may be assessed by audiologists and auditory researchers via indirect measurement of acoustic impedence that yields information about the mechanical properties of the middle-ear transmission system, which may be altered by the acoustic reflex of the muscles of the middle ear.

Technological Influences on Applications

Technological development has led to more direct translation of audiogram data into hearing aid design and adjustment to meet individual needs of hard-of-hearing people. Digital, reprogrammable hearing aids have also been developed. Cochlear implants may be used for infants and older individuals in specific cases of extreme deafness. At this time, such implants do not restore hearing but may transmit impulses from certain audible frequencies that, with therapeutic training, may provide assistance in identifying common sounds such as ringing telephones and doorbells. Cochlear implants may also be helpful in teaching oral speech recognition and production to profoundly deaf individuals. Ongoing technological advances have been yielding even further improvement in the benefit of such implants for some individuals.

SPORT-PERFORMANCE INTERVENTIONS

Conventional wisdom suggests that if athletes want to improve in sport, they should simply practice more. Often, however, what is lacking is not athletes' physical training, but rather their mental skills. Sport-performance interventions focusing on the ability to reach optimal performance states (i.e., the zone), management of arousal and anxiety, self-talk, imagery, goal setting, and modeling have been found to contribute positively to sport performance. Research indicates that performance-enhancement treatment packages that combine two or more of these psychological techniques are particularly effective.

Optimal Performance States

Some sport performances transcend the ordinary. In these instances, athletes may describe themselves as being "in the zone" or as having had a "peak performance." Athletes may also describe this experience as a "flow state," where they are totally involved in the present performance moment. Many sport psychology interventions are designed to help athletes enhance their psychological skills with the ultimate goal of helping athletes reach the peak performance state more often.

Arousal and Anxiety

People who experience anxiety in most situations are considered to have trait anxiety. This anxiety differs from the state anxiety that athletes may experience in sport-performance situations. State anxiety has cognitive (e.g., worry, emotional distress) and somatic (e.g., rapid heart rate, sweaty hands) components. Although a level of physiological arousal is necessary for sport performance, research indicates that excessive anxiety is associated with poor sport performances.

A number of theoretical models have been proposed to explain the relationship between arousal and performance (e.g., inverted-U theory, drive theory, individual zone of optimal functioning, and catastrophe theory). These theories all state that a minimum level of arousal is necessary for sport performance and that the amount of arousal that is needed for optimal performance differs across individuals and sport tasks. All of these theories except drive theory

also posit that both underarousal and overarousal are associated with decrements in sport performance.

Athletes may use several strategies to manage their anxiety and arousal. Cognitive reappraisal approaches work on the assumption that excessive arousal is caused by problematic thought patterns. Changing particular cognitions or the situations that cause these cognitions can help moderate arousal levels, thus enhancing performance. Physiological anxiety-reduction interventions work by affecting physical parameters. For example, techniques such as diaphragmatic breathing and progressive relaxation have been shown to reduce physiological arousal. Hypnosis has also been used to help athletes regulate arousal and enhance performance.

Self-Talk

Self-talk, an overt or covert dialogue with oneself, has been used to help athletes focus attention, correct errors, maintain self-confidence, and moderate activation levels. Research has shown that use of positive or instructional self-talk is associated with enhanced performance. Although negative self-talk may serve a motivating function on occasion, its use has more widely been associated with poor sport performances. The mechanisms by which self-talk affects performance have not been determined.

Imagery

Imagery is the process by which stored sensory experiences are internally recalled and performed in the absence of external stimuli. Imagery can be used to build confidence, practice specific skills, control emotional reactions, improve concentration, practice strategy, and cope with pain and injury. When using imagery, athletes are typically advised to use all their senses, including the kinesthetic (movement) sense, to imagine positive sport outcomes. Many practitioners combine imagery with relaxation, but research has indicated no added benefit for using relaxation in combination with imagery.

Researchers have compared the performance effects of imagery alone to physical practice and to a combination of imagery and physical practice. Results indicate that the combination of imagery and physical practice is generally more effective in enhancing performance than is either physical practice or imagery alone. It should be noted, however, that the utility of imagery in enhancing performance for any particular athlete may depend on the personality, skills, and task involved. As with physical sport skills, the effectiveness of imagery for sport performance enhancement is improved by practice.

Goal Setting

A goal is something that an individual is trying to accomplish, an objective or an aim. A body of research literature in sport and industrial settings has demonstrated that difficult, specific, and challenging goals lead to better performance than do easy goals, vague ("do your best") goals, or no goals. Additional goal-setting strategies have been suggested to enhance performance, including setting long- and short-term goals, setting goals for practice and competitions, writing down goals, setting individual and team goals, developing goal-achievement strategies, providing support for goals, and evaluating goals.

A number of variables that interfere with the effective implementation of goal setting have been identified. Common goal setting problems include (1) failing to set specific, measurable goals; (2) setting too many goals at the beginning; and (3) failing to monitor and readjust goals.

Modeling

Modeling, or observational learning, has been used by athletes to modify sport-related thoughts, emotions, and behaviors. Research indicates that observing models who are learning skills at or near the skill level of the athlete and hearing the feedback that those models receive is more effective in enhancing performance than is watching models who can perform a skill flawlessly. Overall, athletes who are motivated and attend to the model, remember what was presented, and attempt to reproduce what they have observed benefit most from modeling interventions.

Sport Psychology Consultants

Sport-performance intervention services are provided to athletes primarily by sport psychologists. Because sport psychology is an interdisciplinary field, sport psychology practitioners may be trained in psychology, the sport sciences, or both. The Association for the Advancement of Applied Sport Psychology (AAASP) certifies professionals with specialized training and applied experience in sport psychology. Members who are certified consultants are listed on the organization's web site at http://www.aaasponline.org. The United States Olympic Committee also maintains a registry of sport psychology consultants.

Summary

A number of techniques (e.g., management of arousal and anxiety, self-talk, imagery, goal setting, and modeling) have been used to enhance sport performance. Use of these sport-performance interventions may help athletes reach optimal performance states more easily and often. Using sport psychology intervention strategies in combination and practicing them regularly may be particularly useful in enhancing sport performance.

SPORT PSYCHOLOGY

The discipline of sport psychology is dedicated to the investigation of the relationship between psychological factors and exercise and sport. Sport scientists and sport psychologists use physical activity settings to examine issues of competition, performance enhancement, skill acquisition, children's development through sport, team interaction, and the maintenance of physical and mental health.

In 1897 Triplett (1897) conducted what is considered to be the first sport psychology experiment. He found that cyclists competing against other individuals performed better than those performing against the clock or against a standard goal. Coleman Griffith is often credited with founding the first sport psychology laboratory in 1925 at the University of Illinois. He was known for his rigorous investigations of psychomotor skill development, learning theory applied to sport, and the role of personality in performance. In the 1930s he joined the Chicago Cubs organization and became the first psychologist in professional sports.

Development in the field proceeded slowly until the 1960s, when Olgive and Tutko (1966) attempted to integrate psychological assessment and personality theory into sport psychology by developing a test that they hoped would help predict athletic performance. During this same period, Richardson (1967) and other researchers began exploring imagery or mental practice interventions for performance enhancement. However, it was not until 1972 that Richard Suinn (1972) brought sport psychology into contact with contemporary clinical psychology when he applied cognitive-behavioral interventions to athletes in an attempt to improve performance. He reported that training elite skiers in relaxation and imagery skills, combined with a behavioral rehearsal technique, improved performance. Based on Suinn's (1972) work, mental practice interventions for performance enhancement became more intricate and began to resemble the growing body of clinical interventions.

In addition to imagery and mental rehearsal, modern sport psychology encompasses a broad range of interventions directed at improving performance. A major focus of these efforts has been on athletes' ability to manage arousal and anxiety. Many interventions include an anxiety management component intended to allow athletes to modify their level of arousal to match the demands of competition. These interventions mirror the clinical anxiety reduction, stress management, and problem-solving motivational work prevalent with clients experiencing anxiety or depression.

Sport psychologists are also interested in goal setting and its effects on performance. This work has been influenced by industrial-organizational psychology, in which the use of goal setting has become a reliable technique for behavior change. Goal setting is thought to enhance motivation for involvement and promote more positive self-evaluation of training and competitive performance. These changes may facilitate task performance and thus lead to performance change.

Kirschenbaum (Kirschenbaum & Bale, 1980) proposed that athletic skill development can be viewed as a self-regulatory process and that performance is a test of the athlete's skill in self-directed cognition and action. Self-monitoring and self-instruction interventions are used to teach athletes successfully to execute a physical skill, monitor their performance, evaluate their performance against some standard or goal, and alter the execution of physical skills. Such processes are intended to enable athletes to transfer their performance-improvement skills to other tasks and settings.

Although these intervention strategies for performance enhancement should be relevant to athletes of all ages and skill levels, most controlled evaluations of these interventions occur with nonelite and recreational athletes. A quantitative review of such studies found that these interventions are more effective than control conditions (Whelan, Meyers, & Donovan, 1995).

Although performance enhancement is the most visible component of sport psychology, the field is much broader. Another major area of research is sport and exercise behavior across the life span. Sport psychologists are interested in physical skill acquisition and development and focus on such areas as modeling of skills, attention in skill acquisition and performance, and decision making. Other topics include children's psychological development through sport, children's motivation for participation in sport, why children discontinue participation in sport, stress and burnout, and effective coaching practices in youth sport.

Much of sport and exercise takes place in a group or team context. Thus, sport psychologists are also interested in group dynamics. Attention is given to issues such as what makes a group successful, the development and characteristics of leaders of successful groups, and the development and deterioration of group cohesion.

It is accepted that regular participation in sport and exercise enhances an individual's physical health. Sport psychologists also attempt to understand how participating in physical activity affects an individual's psychological well-being. Research has indicated that aerobic exercise is associated with reductions in levels of anxiety and depression. Exercise has also shown positive effects on other aspects of emotional life, including increasing feelings of control as well as improving self-confidence and cognitive functioning. The psychological and physiological benefits associated with exercise throughout the life span support the increasing importance of exercise as one ages.

Exposure at the 1984 Los Angeles Olympic Games brought a dramatic increase in attention to the field of sport psychology, as well as a corresponding increase in the growth of the field. Several journals dedicated to disseminating information in the area of sport and exercise psychology were introduced. These journals include the *Journal of Applied Sport Psychology,* the *Journal of Sport and Exercise Psychology,* and the *Sport Psychologist.* Several professional organizations are dedicated to the advance-

ment of sport and exercise psychology, including the Association for the Advancement of Applied Sport Psychology, Division 47 of the American Psychological Association, and the North American Society for the Psychology of Sport and Physical Activity. Members of these organizations include psychologists and sport scientists who study psychological influences on sport and physical activity. In addition to the dissemination of new and relevant research, these organizations are also committed to establishing and upholding professional standards for the competent and ethical practice of sport psychology.

Although it has been over a century since the initial empirical investigation of psychological influences on sport behavior, the science and profession of sport psychology are broad and vibrant. Performance enhancement may be the most visible domain of sport psychology, but the field includes the study of children and the elderly, teams and leaders, and emotional as well as physical health. With sport and exercise continuing to play a meaningful role in our culture, the study of these behaviors will continue to have a place in the science and practice of psychology.

STATISTICAL INFERENCE

The process of drawing conclusions about a population on the basis of samples (in effect, subsets) drawn randomly from the population is statistical inference. It is widely used in psychology because whole populations can rarely be measured. The logic of statistical inference is the same regardless of the particular problem and techniques employed. On the basis of a sample, the researcher wishes to make statements about what is probably true of the population.

Measures taken on samples are called *statistics;* comparable measures of the population are called *population parameters.* A statistic is calculated on a specific and finite set of data. It will not necessarily equal the population parameter unless the sample is infinitely large, thus including the whole population. Instead, any sample is likely to yield statistics that differ from the true population parameters. The problem becomes one of deciding how accurately each statistic reflects the corresponding population parameters. The application of statistical inference, therefore, requires knowledge of probability theory.

The actual process of statistical inference often begins with setting up the *null hypothesis* (H_0): The researcher assumes that a sample statistic (commonly a mean) was drawn from a population with known parameters. If comparisons between samples are required, the researcher assumes that each group (and its corresponding statistics) was sampled from the same population.

The null hypothesis is retained or rejected on the basis of how likely the observed outcome is. Standardized *test statistics* (such as z, t, F, and chi-square), whose values have known probabilities, are used to evaluate sample statistics in relation to variability. If the difference between groups is largely relative to the amount of variability in the data, the researcher rejects the null hypothesis and concludes that the observed difference was unlikely to have occurred by chance alone: The result is statistically significant. In psychology, researchers customarily reject the null hypothesis if the observed outcome (in effect, the computed test statistic) is so extreme that it could have occurred by chance with a probability of less than 5% ($p < 0.05$).

Because statistical inferences are based on probability estimates, two incorrect decisions are possible: Type 1 errors, in which the null hypothesis is rejected although true, and Type 2 errors, in which the null hypothesis is retained although invalid. The former results in incorrect confirmation of the research hypothesis and the latter in the failure to identify a statistically significant result.

A. Myers

STATISTICAL POWER

Hypothesis testing involves contrasting two rival hypotheses. The null hypothesis specifies that nothing special is happening. The alternative hypothesis specifies that something is happening. For example, the null hypothesis might state that two groups have the same mean or that the correlation between two variables is zero. The alternative hy-

pothesis can be directional or nondirectional. A directional hypothesis states the direction of the phenomenon; for example, Group 1 has a higher mean than Group 2, or the correlation is larger than zero. A nondirectional hypothesis does not specify the direction of the effect but states that the effect does exist; for example, the two groups have different means, or the correlation is not zero. Statisticians begin by assuming that the null hypothesis is true and reject the null hypothesis only if the observed results are quite unlikely under this assumption. Based on some assumptions concerning the study, for example, a random sample, and a normally distributed dependent variable, the researcher can calculate the probability of rejecting the null hypothesis when it is true (alpha) and the probability of rejecting the null hypothesis when the alternative hypothesis is true (the statistical power of the test). Because the researcher wants to reach the correct conclusion, good studies are designed to have low alpha and high power. A correct null hypothesis is unlikely to be rejected if alpha is low, and a correct alternative hypothesis is likely to be concluded if power is high.

Researchers generally use an alpha level that is no larger than .05. They reject the null hypothesis only if the sample results are in the extreme 5% of the range of possible outcomes if the null hypothesis were true. When the null hypothesis is rejected, the researcher concludes that the results are statistically significant and generally specifies the significance probability, that is, the alpha associated with the outcome. For example, the researcher may conclude that the correlation is significant, $p < .01$, meaning that the null hypothesis of zero correlation could be rejected using an alpha less than .01. A more extreme result has a smaller significance probability, such as $p < .005$ or $p < .0001$.

Because the traditional approach is designed to keep alpha low, researchers must be careful to ensure that the power of their tests is reasonably high. Power estimates can be made before data are collected, and research studies with insufficient power can be redesigned to improve power. There are four principal strategies to increase power: increase alpha, specify directional hypotheses, increase the sample size, and increase the effect size.

Increasing alpha increases power. Researchers are more likely to reject the null hypothesis when alpha is higher, so they become more likely to conclude that a correct alternative hypothesis is true. A second way to increase power is to specify directional hypotheses. This allows the researcher to concentrate the alpha risk at only those outcomes that are consistent with the directional hypothesis. For example, a test on a correlation coefficient using a nondirectional hypothesis and an alpha of .05 might reject the null hypothesis for observed correlations below –.60 or above +.60. Outcomes between –.60 and +.60 are expected to occur 95% of the time when the null hypothesis is true, whereas outcomes outside of this range are expected only 5% of the time in this situation. If the researcher could specify a directional hypothesis, such as a positive correlation, the decision might be to reject the null hypothesis for all correlations above +.55. If the observed correlation were .58, the researcher could not reject the null hypothesis for the nondirectional hypothesis but could reject the null hypothesis for the directional hypothesis, giving the test more power. (Unfortunately, if the directional hypothesis postulates the wrong direction, the researcher will not find significant results and will be in error.) A third way to increase power is to increase the sample size. Statistics based on larger samples are more stable, allowing more precise estimation of population characteristics. This increased precision makes it more likely that correct alternative hypotheses are detected. The last way to increase power is to increase the effect size. The effect size is the strength of the relationship being studied. For example, to demonstrate that different types of birds have different sized eggs, one could compare ostriches to hummingbirds, with an enormous effect size, rather than compare chickens with ducks, with a smaller effect size. Studies examining large effect sizes are more likely to reject the null hypothesis, giving them more power.

Researchers want studies with low alpha and high power so that they are likely to reach accurate conclusions. They generally control alpha by not allowing it to exceed .05, and they have strategies to increase power. A well-designed study may have a larger alpha, a directional hypothesis, a large sample size, or a large effect size. Researchers consider all these options when they design studies so that they are likely to reach accurate conclusions about the variables being studied.

STATISTICAL SIGNIFICANCE

Researchers often employ statistical tests to evaluate the results of their studies. The term *statistical significance* is used in relation to the use of these tests. If a researcher's results or data reflect statistical significance, an interpretation that the outcomes are not likely due to chance is thought appropriate.

Statistical tests basically evaluate the results of an investigation in light of chance occurrences. These tests permit the researcher to assess the probability that such results might have been due to chance. For example, one might be comparing the recall performance of two groups and find that there were mean correct responses of 25 and

42 for Groups A and B respectively. It is important for the researcher to determine how frequently such differences might be expected by chance alone.

The term *statistically significant* is applied to results where the probability of chance is equal to or below an agreed-upon level. Most psychologists accept a 5% (or lower) probability of chance as being statistically significant. This is typically reported as $p < .05$, which means that if the study were replicated 100 times, these same results would attain fewer than five times due to chance. Another frequently used level of significance is the 1% level, which is generally reported as $p < .01$. In this case one would expect to observe the results by chance only one time out of 100. These significance levels are based on convention and are widely accepted, but they are not derived from mathematical justification. There are some differences among various disciplines regarding what is considered statistically significant.

Statistical significance may be determined for both tests of difference and tests of relationship. For difference questions, one can establish how often such differences would be obtained due to chance. For relationship questions, one can assess how often a given relationship level (correlation coefficient) would be observed due to chance. Statistical significance and the resulting decision regarding the likelihood of an effect due to chance are influenced considerably by the research design employed.

STEPCHILDREN

Studies of stepfathers suggest that the entrance of a stepfather into a previously father-absent home has a positive effect on boys' cognitive and personality development; the effects on girls' cognitive and personality development are virtually uncharted. In one observational study of family interaction in stepfather, divorced-mother custody, and intact families, boys in stepfather families showed more competent social behavior than did boys in intact families. By contrast, girls in stepfather families were observed to be more anxious than girls in intact families. Boys showed more warmth toward their stepfather than did girls. Boys in stepfather families also tended to show more mature behavior than did boys from divorced homes.

In a recent comparison of children in father-custody, stepmother, and intact families, observations indicated some consistent sex differences: Boys were observed to be less competent during social interaction with both their stepmother and their biological father than were girls. Combined with the data collected by Santrock and colleagues on stepfather families, an intriguing scenario of sex of child, sex of custodial parent, and type of stepparent family unfolds. During the early years of the stepfamily, children are confronted with many changes, adjustments, and possible new attachments. The disequilibrium created by the father's remarriage seems to produce a positive effect for his daughter but a negative effect for his son. His children have already undergone at least one major traumatic change in their lives, that is, the severing of their parents' marriage. Several years after the divorce, boys whose fathers have obtained custody seem to have adjusted well, and the same is true for girls whose mothers have custody. The entrance of a stepmother may produce conflict for a boy, and the entrance of a stepfather may do the same for girls.

John W. Santrock

STEPPARENTS

The number of remarriages in which children are involved has been growing steadily. Approximately 10% to 15% of all households in the United States are comprised of stepfamilies. A review of the stepparent literature presents mixed findings. Some researchers have found no differences between stepparent and intact families, whereas others have found significant differences suggesting that stepparent families have more difficulties and problems.

Although an extensive amount of information about divorced families has been obtained in recent years, the efforts to understand the psychological climate of stepparent families have not been as extensive. One recent investigation represents the first attempt to observe actual social interaction in stepparent families. The most consistent findings suggested that the stepfather and biological mother showed more competent parenting when the child was a male than was the case for comparable intact families. Further analyses indicated that, in the sample studied, mari-

tal conflict was greater in the intact-family boy's home than in the stepfather boy's home. These data clearly suggest that parenting techniques in stepparent families are not necessarily inferior to those in intact families.

There are virtually no data that compare stepfather or stepmother families with divorced-mother or father-custody families. Mothers with custody seem to have a particularly difficult time with sons, and some evidence suggests that fathers with custody may be more competent in rearing sons than daughters.

John W. Santrock

STIMULUS GENERALIZATION

Stimulus generalization refers to a tendency to respond to a stimulus similar in character to, and yet discriminably different from, a stimulus to which the animal was originally trained. Pavlov (1927) and his associates first demonstrated this phenomenon in laboratory experiments with dogs. After experiencing a succession of paired stimuli, such as a tone with food, the dog eventually comes to salivate reliably to the tone. If a test phase is instituted following this training so that the dog experiences tones varying in similarity to the original tone but without the food, its responding to the new stimuli declines as the test stimuli became more dissimilar to the training stimulus. This outcome is referred to as stimulus generalization, and this gradient of responding reflects the extent to which the training stimulus controls responding. A flat gradient implies that the original stimulus exercises little control over the response; in other words, there is complete generalization. In contrast, a steep gradient suggests little or no generalization; responding is confined largely to the training stimulus. Although the demonstration of generalization gradients appears straightforward, their measurement, the variables that affect them, and their role in the learning process are complex.

Stimulus similarity is usually measured with reference to some physical dimension of the stimulus such as wavelength, size, or intensity, although psychophysical units are used occasionally. The number of responses made to each test stimulus results in an *absolute* generalization gradient. Absolute gradients can be transformed into *relative* gradients by expressing responses to a test stimulus as a proportion of the total number of responses made to all stimuli during the test phase or to responses made previously to the training stimulus. Relative gradients correct for conditions in which wide variation in responding exists among subjects. Which type of gradient to use depends on whether the scale corrects for floor or ceiling effects, remains unchanged when a manipulated variable has no effect on the gradient, or makes the results consistent with other experiments. A common practice is to report both types of gradients.

Schedules of reinforcement, degrees of learning to the training stimulus, and the animal's motivational state influence the extent to which responses generalize to other stimuli. In early studies, reinforcement followed the training stimulus on every occasion. A disadvantage with this procedure was that limited responding occurred to test stimuli because each test trial was also an extinction trial. To offset extinction effects, researchers began reinforcing training stimuli intermittently; however, it was soon apparent that reinforcement schedules directly affected the generalization gradients. Schedules influence the extent to which incidental contextual cues present during the training and test phases affect responding. For example, when the average time interval between reinforcements is lengthened, responding to test stimuli increases, which results in flatter gradients (Haber & Kalish, 1963; Hearst, Koresko, & Poppen, 1964). Presumably, response-produced stimuli that occur during the interval between reinforcements provide additional information as to when the reinforcement will occur, and this stimulation is still present during the generalization test phase (Thomas & Switalski, 1966).

As a general rule, the more experience with the training stimulus prior to generalization testing, the less generalization is observed. In effect, more training results in a steeper gradient (Hearst & Koresko, 1968; Razran, 1971). An exception occurs when external stimulation is uniform and proprioceptive cues control responding. Under this condition the gradient is flat regardless of the training received on the original stimulus (Margoluis, 1955; Walker & Branch, 1998).

Interest in motivational effects on stimulus control stems from Hull's (1943) hypothesis that motivation and habit combine multiplicatively to determine performance. This counterintuitive notion predicts that performance improves with higher levels of motivation, implying higher and steeper absolute gradients with increasing motivation. Although the results of several studies support the hypothesis (e.g., Newman & Grice, 1965), others report contrary findings (e.g., Broen, Stroms, & Goldberg, 1963). Resolution of this issue came from the recognition that motivation's effect on stimulus generalization depends on the discriminability between training and test stimuli. If the discrimination between training and test stimuli is easy, high levels of motivation produce steep slopes. However, when the stimuli are difficult to discriminate, higher levels of motivation result in flatter gradients (Kalish & Haber, 1965).

Gradients may be either excitatory or inhibitory. Excitatory gradients are generated by a decline in responding as test stimuli become more dissimilar to the training stimulus. In contrast, stimuli predicting the absence of reinforcement control the tendency not to respond, and this control can be measured by an increase in responding as the similarity between the original inhibitory stimulus and the test stimuli decreases (Honig, Boneau, Burstein, & Pennypacker, 1963; Jenkins & Harrison, 1962; Karpicke & Hearst, 1975).

Learning theories assign an important theoretical role to stimulus generalization. It not only facilitates survival—behavior resulting in finding food, securing a mate, or escaping a predator may generalize to new but similar situations—but it is also viewed as a process that underlies more complex learning phenomena (Hull, 1943; Spence, 1936).

Conditioning-extinction theory is a major representative of this approach (Hull, 1943, 1952; Spence, 1956). The theory assumes that excitation (a tendency to respond) develops to a stimulus paired with reinforcement and that the excitation generalizes to other similar stimuli. Similarity, inhibition (a tendency not to respond) accrues to the stimulus predicting the absence of reinforcement, and the tendency not to respond also generalizes to similar stimuli. If the original excitatory and inhibitory stimuli are situated along the same physical continuum, there may be an overlap of excitatory and inhibitory gradients. This overlap in the gradients allows for the arousal of contradictory impulses of responding or not responding among the stimuli. Eventually, the animal chooses one stimulus over another because the net excitation (excitation minus inhibition) of the selected stimulus exceeds the net excitation of the unselected stimulus. Conditioning-extinction theory was extended with some success to complex discrimination phenomena such as the peak shift effect, transfer of discrimination, and transposition (Hanson, 1959; Logan, 1971; Spence, 1942).

Even so, the original cast of the theory can account neither for the selective nature of associations nor for the development and utilization of cognitive strategies. In its original form it assumed that any detectable stimulus serving as a signal for reinforcement or nonreinforcement would acquire excitatory or inhibitory properties. But this is not the case: The organization of the neural apparatus determines whether associations between conjoint events will be formed (Garcia & Koelling, 1966), which determines whether stimuli activate tendencies to respond or not. Moreover, the formation of associations depends on the animal's previous learning history. Stimuli that provide no new information about impending events or that are less reliable or valid predictors of reinforcement form either no or weakened associations with significant and consequential events that they precede, as is the case in blocking (Kamin, 1968) and learned overshadowing (Rickert, Lorden, Dawson, Smyly, & Callahan, 1979; Wagner, Logan, Haberlandt, & Price, 1968). The decrement in responding to either redundant or less valid stimuli in the blocking and learned overshadowing paradigms is much greater than the theory predicts. Although efforts to accommodate these phenomena have met with some success (e.g., Rescorla & Wagner, 1972), this version has difficulty predicting the magnitude of generalization decrements in related phenomena (e.g., external inhibition).

More recently, Pearce (1987) suggested that the inability of previous theories to accommodate some of these findings rests on their assuming that the context in which the stimulus is presented has no effect on the stimulus's capacity to elicit responding. Pearce's model argues that context is crucial in determining the extent of generalization. The model posits a limited-capacity memory buffer that stores the current overall pattern of stimulation. If this pattern is followed by a reinforcing event, the representation is stored as a stimulus-reinforcement association in long-term memory. On a later occasion, any change in context results in a stimulus pattern that produces a different content in the buffer, resulting in the formation of a slightly different association. The strength of responding is determined by the correspondence or similarity between the original and the later association.

Pearce's account of stimulus generalization accommodates a wide range of phenomena. When events only moderately correlated with an outcome are paired with either an event that perfectly predicts the occurrence of an outcome or one that predicts its absence, humans judge such events as less valid than they actually are, a finding consistent with Pearce's model (Baker, Vallee-Tourangeau, & Murphy, 2000). Nakajima (1998) trained pigeons to arrays of compound stimuli. In the test phase, during which the positive and negative features of these stimuli were rearranged in different ways, responses to the new compounds were consistent with deductions from the model. Other results that are also consistent with the model have shown that a cue's validity in signaling impending events is jointly determined by the cue and its context (Murphy, Baker, & Fougnet, 2001).

Although the scope of associative theory can apparently be widened to accommodate processes of associative selection, understanding the relation between cognitive processes and associative mechanisms appears necessary to provide a complete account of discrimination and generalization. For example, applying rules to solve discrimination problems may result in behavior that cannot be accommodated in current theories. Learning set reversals was an early example. Bessemer and Stollnitz (1971) found that monkeys abandon response tendencies associated with reinforcement and choose objects previously paired with nonreinforcement based on information from the immediately preceding trial. These data suggest that the use of generalization as an explanatory device requires specifying the conditions under which it and these more complex processes interact.

STRESS CONSEQUENCES

Stressors encountered by humans may comprise major insults ranging from the loss of loved ones, unexpected calamities (hurricane, tornado, flood, war, accident), and financial distress, or they may involve a series of day-to-day annoying experiences. Both the severe and less intrusive stressors may influence physiological and behavioral processes, and both have been implicated in the provocation or exacerbation of a large number of illnesses, including the classical psychosomatic disorders and depressive illness, cardiovascular disease, as well as those that involve immune dysfunction.

The *stress response* has been considered as the homeostatic or adaptive biological and/or behavioral response (allostasis) to a stimulus that is appraised as being aversive. In general, stressors elicit behavioral responses to attenuate the challenge, and concurrently peripheral and central nervous system neurochemical alterations occur that may be of adaptive significance. Among other things, they may be essential in order that animals be prepared to respond appropriately to impending as well as ongoing stressors. Moreover, these biological changes may be necessary for the

organism to react with appropriate emotional and behavioral responses, initiate and maintain effective defensive strategies, initiate processes that will protect the organism from pathogenic stimuli, limit overreaction of other neurochemical systems that might themselves lead to pathology, and minimize the physical and psychological impact of the aversive stimuli.

One of the fundamental, and most frequently examined, physiological responses elicited by stressors is the activation of the hypothalamic-pituitary-adrenal (HPA) axis. This system is readily stimulated not only by psychological or physical stressors but also by systemic stressors (e.g., immune activation), although they may do so by activation of a different neural circuit. Ordinarily, when a stressor is encountered, the paraventricular nucleus of the hypothalamus is activated, giving rise to the release of corticotropin-releasing hormone (CRH) from terminals located at the median eminence. This hormone stimulates the anterior pituitary, promoting the release of ACTH into circulation, which in turn stimulates the release of cortisol (or corticosterone) from the adrenal cortex. Cortisol is thought to play an integral role in facilitating adequate responses to stressful events and may serve to prevent overshoot of immune reactions.

It would be most adaptive for certain neurochemical responses to be mounted rapidly, regardless of the psychological attributes of the stressors (e.g., controllable vs. uncontrollable; predictable vs. unpredictable). Those systems that are necessary for immediate responses to contend with stressors (e.g., activation of the sympathetic nervous system), and even fundamental immune responses that act against pathogenic stimuli, should react comparably to both controllable and uncontrollable stressors. In contrast, those central systems that are uniquely involved in the appraisal of stressors would be influenced by the psychological attributes of the stressor. It is well known, for instance, that uncontrollable stressors provoke behavioral disturbances (reminiscent of depressive states) that are not as readily induced by controllable stressors. Some investigators have interpreted these differences as reflecting learned helplessness provoked as animals learn that they have no control over their environment. Others, however, have attributed the behavioral disturbances to the neurochemical alterations that may be unique to uncontrollable aversive events. Generally, stressors promote increased utilization and synthesis of neurotransmitters within particular regions of the brain. These include norepinephrine (NE), dopamine (DA), serotonin (5-HT), acetylcholine (ACh), GABA, and various peptides. Under conditions where behavioral control over the stressor is unavailable, greater strain is placed on neuronal systems, and consequently they may become overly taxed. The excessive utilization of neurotransmitters (or the decline of the transmitter secondary to excessive utilization) in certain brain regions may result in a net decline of the transmitter, thus leading to greater vulnerability to pathological states.

In addition to the immediate effects, stressful events may proactively influence the response to later stressor experiences. It seems that stressors may result in the sensitization of processes that promote central neurochemical functioning so that reexposure to the same stressor (and even to alternate stressors) at a later time may result in the neurochemical changes occurring more readily. Thus, such sensitization processes may contribute to the induction of stressor-related illnesses even at lengthy intervals following a trauma and may be responsible for the high rates of relapse associated with illnesses such as depression. It is important to note that in addition to simple sensitization effects, cross-sensitization has been observed so that stressors increase the response to drugs such as amphetamine and cocaine. Likewise, it has been shown that the administration of cytokines, signaling molecules of the immune system, may result in a sensitization effect so that the response is vastly increased on their reexposure. Thus, in considering the impact of stressors, one should consider not only the immediate repercussions but also the increased vulnerability that develops to later stressor experiences. It is also important to note that the sensitization grows with the passage of time and hence may be a contributing factor to illnesses that likewise appear to be linked to temporal processes (e.g., posttraumatic stress disorder).

The proactive effects of stressors are particularly notable among animals that had encountered distress early in life. For instance, studies in animals have shown that when pups are separated from the mother for several hours a day during early postnatal development, the adult response to stressors is particularly pronounced. In contrast, those animals that received early life stimulation (particularly those that received frequent licking and grooming) tended, as adults, to be more resilient to the impact of stressors.

Intuitively, one would imagine that the behavioral and neurochemical impact of acute stressors would be exacerbated with repeated stressor experiences. In fact, however, following chronic stressor regimens, some of the behavioral disturbances ordinarily provoked in rats and mice may be attenuated. This sort of adaptation is not limited to the behavioral effects of stressors but has been reported also with respect to physiological processes, including neurochemical and immunological functioning. For instance, the NE reductions ordinarily observed after acute stressors may be absent following protracted or repeated insults owing to a compensatory increase in the synthesis of the transmitter. As the stressor experience continues, however, the wear and tear on the system may become excessive (allostatic load) and may lead to increased vulnerability to pathological outcomes. It is thought that under such conditions vulnerability is increased with respect to mood, neurodegenerative, and immunologically related disorders.

STRESS RESPONSE

There are three current stress model paradigms—environmental, psychological, and biological. Regardless of its etiology, stress exerts a powerful influence on the physiology of every bodily system via its impact on both the cognitive and physiological processes of the central nervous system (CNS). In a normal and beneficial stress response, the challenge is resolved or adapted to, and functioning returns to an appropriate base level. When these responses do not maintain homeostasis and resistance fails due to inadequate, inappropriate, or excessive activation of the compensatory systems, there is high risk of physical and psychological damage.

Due to its variety of specialized extero- and interoceptive sensory transducers and its unique integration capacity, the CNS plays a major role in the defense against and adaptive response to stress. Stress responses begin with cerebral alterations that lead to behavioral changes—in content, emotions, and speech—and alterations in central and peripheral neurotransmitters that effect changes in the physiology of other organ systems. The manifold defense mechanisms directed against stressors to which an organism is subjected form a single and highly integrated regulatory system. This system includes (1) the complex subcortical CNS networks linking the integrative centers of the hypothalamus, brain stem, and limbic system; (2) their major nervous outputs through the peripheral nervous system controlling behavioral and neurovegetative adaptive responses through sympathetic and parasympathetic components; (3) the neurohormonal outputs originating in the endocrine neurons of the hypothalamus; and (4) the immune system.

The normal stress response involves synergistic activation of the sympathetic-adrenal medullary (SAM) and hypothalamic-pituitary-adrenocortical (HPA) systems through their primary CNS effects of corticotropin-releasing hormone and factor (CRH and CRF, respectively). Central CRF systems supply the critical signal for activation of behavioral, emotional, autonomic, and endocrine responses to stressors. They activate cortical limbic, hypothalamic, and pituitary mechanisms that promote adaptive changes in the face of an acute threat. Aggression, the focus of attention on the threat, arousal, vigilance, and the shutdown of sexual and feeding behaviors result. As the adrenal medulla secretes catecholamines and the adrenal cortex secretes glucocorticoids, blood flow is increased to the CNS, and fuel is made available for immediate skeletal muscle activity, in part through gluconeogenesis. Glucocorticoids also cause immunosuppression, theoretically inhibiting the inflammatory response to any injury endured during the threat and postponing it until the organism has escaped to safety. Although this latter effect of glucocorticoids is useful during immediate threat, it may provoke or sustain illness through immunosuppression in the setting of persistent, chronic stress. Glucocorticoids also appear to be critical in the shutdown of the stress response. They suppress the effect of CRH and very likely inhibit catecholamine activity in the locus ceruleus in the SAM system.

Of those two systems, the HPA system exerts significant homeostatic control over the stress response. There is clear evidence of HPA activity in the context of overwhelming, chronic threats and distress, including major depression, where hypercortisolism and other findings support HPA activation (Leonard & Song, 1996). The effects of chronic stress differ from the sequelae of acute, limited stress. A state of persistent, uncontained stress is pathological, and loss of neurobiological control over the stress response could be a factor in the development of cancer, various psychiatric disorders (e.g., depression, posttraumatic stress disorder [PTSD], and alcohol addiction; Ehlert, Gaab, & Heinrichs, 2001), and other medical conditions (hypertension, asthma, and gastrointestinal and reproductive dysfunction; Brier, 1989).

Repeated stress and resultant hypercortisolism have consequences for brain function, especially the hippocampus because of its high concentration of glucocorticoid receptors. The hippocampus is essential for learning through its effect on episodic and declarative memory and is especially important for the memory of context of the time and place where events with a strong emotional basis occurred. Thus, hippocampal impairment decreases the reliability and accuracy of such memories. This may contribute to the degree to which events may be perceived as stressful when, had context memory functions been normal, the circumstances of those events might have been perceived as nonthreatening. The mechanism for stress-induced hippocampal dysfunction and memory impairment is twofold. First, acute stress elevates adrenal steroids and suppresses neuronal mechanisms that subserve short-term memory involving the hippocampus and temporal lobe. These effects are reversible and relatively short-lived. Second, repeated stress causes atrophy of dendrites of pyramidal neurons in the CA3 region of the hippocampus, doing so through a mechanism involving glucocorticoids and excitatory amino acid and other (e.g., serotonin) neurotransmitters released during and in the aftermath of stress. Although this atrophy is reversible as long as stress is short-lived, prolonged stress lasting many months or years may, among other things, be capable of killing hippocampal neurons (Sapolsky, 1996). Stress-related disorders such as recurrent depressive illness, PTSD, and Cushing's syndrome are associated with atrophy of the human hippocampus measured by magnetic resonance imaging (Bremner, 1999).

The hippocampus is also a regulator of the stress response and exerts a largely inhibitory effect to promote shutoff of the HPA axis stress response. Recent evidence suggests that the hippocampal influence on the hypothalamic CRF neurons is via the bed nucleus of the stria terminalis and involves the regulation of an inhibitory output to these neurons (Herman & Cullinan, 1997).

Other areas in the limbic system (e.g., cingulate gyrus and amygdala) and frontal brain regions also have higher

concentrations of glucocorticoid receptors. Although less is known about the impact of glucocorticoids in these regions, the same general picture as in the hippocampus may hold, particularly early in life when these regions are developing rapidly and forming interconnections (Hatalski, Guirguis, & Baram, 1998; Schneider, 1992).

A third stress response component is composed of endogenous opioid (EO) release. Hypercortisolism in the HPA system is accompanied by activation of the EO system. Stress-induced analgesia involving EO peptides has been demonstrated in animals and humans, both in association with nociceptive stimuli and in response to nonpain, cognitive stress. Since the original demonstration of the EO receptor by Pert and Snyder in 1973, various opioid peptides such as β-endorphin and enkephalins have been identified. These EOs are produced in sites including the pituitary and adrenal glands, linking the EO system to the HPA and SAM components of the stress response. Theoretically, release of EOs modulates emotional response to stressors through calming effects by reducing pain and perhaps by altering immune function.

There is now clear evidence of reciprocal interactions between the immune system (IS) and the CNS (Webster, Tonelli, & Sternberg, 2002). Most hormones secreted during the stress response have immunologic effects. Anatomical and functional connections have been demonstrated between the IS and the CNS; and cytokines, neuropeptides, and neuromediators have been shown to modulate cells of the two systems via receptors on neurons and lymphocytes. It has become apparent that the IS and CNS are tightly interconnected and interdependent and that they interact during development and in the induction of CNS pathology (Herbert & Cohen, 1993). It has also been extensively documented that individuals experiencing acute, subacute, and chronic psychological stress are immunodepressed and that stress is linked with higher morbidity.

Interindividual variation in stress responsiveness depends on three principal factors. The first is how the individual perceives and interprets the situation. If the stimulus is seen as a threat, then behaviors and physiological responses ensue that can have further consequences; otherwise, responses either are not precipitated or differ from stress responses and are also more benign. The second aspect of individual differences concerns the condition of the body itself. For example, metabolic imbalances leading to obesity and diabetes can increase an individual's vulnerability to stress and may have a genetic component (Brindley & Rolland, 1989). The ability of individuals to cope with the same stressor may be vastly different. Differences in coping skills depend on a combination of many factors, including genetics, training, religion, environment, education, coping skills, gender, age, self-esteem, past experiences, nationality, family stability, social relationships, and perceived social supports.

The final major factor is the nature of the stressor itself. Stressors can be characterized in a variety of ways: by etiology (e.g., physical, emotional-cognitive, or both); by duration (acute, chronic, or both); by complexity (due to a single event or multiple factors); by temporal nature (from the past, present, or future); or by intensity (mild, moderate, or severe). The pattern in which stressors are presented also impacts responses. Baum, Cohen, and Hall (1993) categorized stress duration through the use of a $2 \times 2 \times 2$ matrix that crossed duration of the event, duration of the perceived threat, and duration of stress response. This matrix suggests a more sensitive approach to understanding the role of stress duration (e.g., the difference between a persistent stressful event that is no longer appraised as stressful or responded to with a stress response, and a stressful event that has terminated but continues to be appraised as a stressful event and is responded to with a stress response, e.g., a traumatic experience).

The idea that cumulative levels of stress may have deleterious effects on health and longevity has long intrigued investigators dating from the early work on homeostasis and continuing with the work of Cannon (1939), Selye (1956), and others on the pathologic consequences of excessive physiologic activation. However, much of the early work focused on the effects of stress on specific, individual biologic parameters and associated health consequences. Recently, McEwen and Stellar (1993) broadened Sterling and Eyer's (1988) concept of allostatic load to mean a cumulative, multisystem view of the long-term effects of the physiologic response to stress. McEwen (1998) described four types of allostatic load situations, each with a differing potential for short- and long-term effects: (1) frequent stress exposure with appropriate adaptation; (2) lack of adaptation to the same repeated stressor; (3) prolonged response due to delayed or absent shutdown after the stressor is terminated; and (4) inadequate responses to the stressor that trigger compensatory increases in others.

Stress is universal: It is found in every person, every culture, and every generation. It is a broad-based phenomenon that exists as a continuum. Individuals showing various stress response patterns are likely to be distributed differently across gradients of socioeconomic status but not confined exclusively to one part of the gradient. Thus, it is important to distinguish between characteristics of groups and the vulnerability of individuals. Further work is necessary to understand the various forms of stress responses and their relationship to health and disease in individuals.

STRIATE CORTEX

The striate cortex (area 17 or V1) is the primary visual cortex involved in conscious visual perception. It is located on both banks of the calcarine fissure in the occipital lobe. Each hemisphere has a precise, retinotopic representation of the contralateral visual field. The vertical meridian is represented at the V1/V2 (secondary visual cortex) border; the horizontal meridian bisects it midway; and the contralateral lower and upper visual fields are found in the cuneus and lingual gyrus, respectively. The map is skewed, favoring central visual field representation, and magnification changes from ~4 mm of cortex/degree at 1° centrally to ~0.5 mm/degree at 25° from the center of gaze.

The striate cortex is ~1.5 to 2 mm thick and has six cellular layers (I to VI). Layer IV (granular layer) is expanded into IVA, IVB, and IVC (IVCα and IVCβ). IVA and IVCβ receive input from the parvocellular layers of the lateral geniculate nucleus (LGN), whereas IVCα receives magnocellular LGN input. Layer IVB is the stripe of Gennari and contains cortico-cortical fibers. The koniocellular (small-celled) LGN layers project to layers II and III puffs. Signals from layer IV are relayed to supragranular and infragranular layers. Supragranular neurons project to other cortical areas, whereas infragranular neurons project primarily to the superior colliculus and the LGN.

While the receptive fields (RFs) of retinal ganglion cells and LGN neurons are circular with concentric center-surround antagonism, only the first-stage cortical neurons in layer IVC and layers II and III puffs have similar RFs. Most striate cortical neurons have elongated RFs and respond best to lines, bars, slits, borders, and edges with a specific orientation. They also prefer moving or flickering light stimuli than stationary lines, and layer IVB cells are also direction selective. Hubel and Wiesel (1968) described simple and complex units in the striate cortex of cats and monkeys. Simple cells receive input from three or more LGN neurons and have discrete ON and OFF RFs that respond to stimuli of specific orientation and position. Complex cells receive input from a number of simple cells with the same orientation preference. Their RFs do not have discrete ON and OFF regions, and they respond to stimuli of specific orientation and width, but not necessarily of specific length and position. These and other properties uncovered by many investigators characterize cortical neurons according to their preference for color, direction, orientation, high or low spatial frequencies, eye dominance, and contrast sensitivity.

The striate cortex is organized into vertical columns extending from layer I to VI, in which cells share similar functions. Ocular dominance columns (ODCs) segregate cells dominated by one or the other eye. Although most cells are binocular, those in layer IV are strictly monocular. Orientation columns partition cells by orientation preference (e.g., vertical, horizontal, and oblique at various angles). ODCs are ~0.5 mm wide in humans, and orientation columns are only ~50 μm in diameter. These two sets of columns interdigitate with one another and with other functional columns, such as those for color and spatial frequencies.

The primate striate cortex has an extremely regular array of cytochrome oxidase-rich zones in layers II and III. Cytochrome oxidase is a mitochondrial energy-generating enzyme, and these regions are metabolic hot spots, named puffs, supragranular blobs, dots, patches, or spots. Puffs

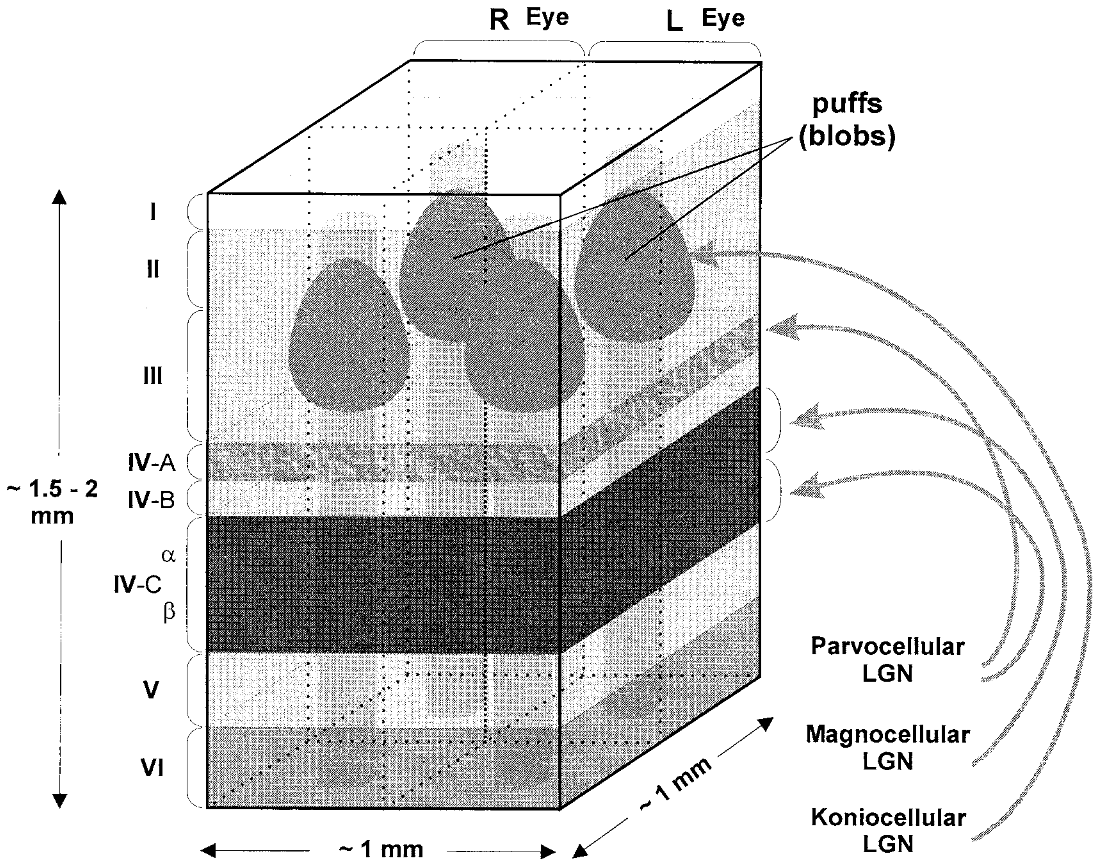

Figure 1. A schematic diagram of the striate cortex showing cytochrome oxidase-rich (darker) and -poor regions. Layers IVC, IVA, II/III puffs (blobs) and, to a lesser extent, VI receive geniculocortical projections and are moderately to intensely labeled. Each puff is centered on an ocular dominance column (right-eye R or left-eye L), the very center of which also exhibits slightly higher levels of cytochrome oxidase (rod-like shading from layers II to VI). Orientation columns (not shown) are intermingled within each ocular dominance column. A module contains the minimal and necessary sets of orientation columns, ocular dominance columns, and puffs/blobs to analyze a small locus in the visual field.

are laid down before birth in the macaque but after birth in the human. They receive direct geniculate input from the konio layers and are centered on ODCs. Cells within puffs have RF properties that are distinctly different from those in the interpuffs.

Puffs	Interpuffs
Cytochrome oxidase-rich	Cytochrome oxidase-poor
Monocular	Binocular
High spontaneous activity	Low spontaneous activity
Receptive field mostly circular; color-opponent center-surround	Receptive field rectangular; ON- or OFF-center with antagonistic flanks
Orientation-nonspecific	Orientation-specific
Respond to low spatial frequency gratings	Respond to high spatial frequency gratings
Greater color selectivity	Lesser color selectivity
Input: IVCβ and koniocellular LGN layers	Input: IVCβ
Output: mainly thin stripes of V2	Output: mainly interstripes of V2

A 1 to 2 mm^2 piece of visual cortex would contain sufficient neural machinery to process visual signals from a particular point in the visual space, such as size, shape, color, luminance, movement, and depth. It would include the minimal and necessary sets of ODCs, orientation columns, and puffs (blobs) centered on ODCs. This is known as a cortical module.

The major neurotransmitter of cortical projection neurons is glutamate, the universal excitatory transmitter. GABA is the key transmitter of inhibitory interneurons. Other neurochemicals, such as calbindin, calmodulin, neuropeptide Y, parvalbumin, somatostatin, substance P, and nitric oxide probably serve modulatory roles.

Information from the geniculocortical pathway is channeled to over 30 extrastriate cortical areas in the occipital, parietal, and temporal lobes. These multiple streams process different attributes of the visual stimuli: color, contrast, form, and movement. The "what" (or ventral) stream for object recognition is channeled to the inferotemporal cortex. It is subdivided into two parvocellular (P) streams: one for color, form, and movement, the other for color and contrast. The "where" (or dorsal) stream is the magnocel-

lular (M) stream for spatial localization and is concerned with contrast, movement, and stereopsis. It goes to the parietal cortex. The koniocellular stream mediates another pathway via the cortical puffs. However, much cross talk exists among visual cortical centers.

If the signal from one eye is disrupted by infection, patching, strabismus, astigmatism, lesion, or other abnormalities during the critical period of postnatal development, cortical neurons that receive input from the nonaffected eye will become dominant and command more synaptic space at the expense of cells representing the deprived eye. Behaviorally, the individual may suffer from amblyopia, poor depth perception, poor pattern perception, or frank blindness in that eye. It is interesting that binocular deprivation is less detrimental than monocular deprivation because of the importance of binocular competition.

Recent work has demonstrated that mature neurons remain capable of responding to altered functional demands (reviewed in Wong-Riley, 1994). When impulse activity of one eye is blocked in adult monkeys, deprived cortical neurons down-regulate their cytochrome oxidase and other neurochemicals (GABA, glutamate, NMDA receptors, nitric oxide synthase, and others). Synaptic reorganization can also occur in the mature visual cortex, and changes are reversible when there is no denervation.

In recent years, functional magnetic resonance imaging (fMRI) has uncovered in the living human visual cortex many analogous subdivisions previously mapped in the macaque brain.

STRONG INTEREST INVENTORY

The Strong Interest Inventory (SII) was published in 1995, the latest in a series of revisions of a test originally developed by E. K. Strong, Jr., in the 1920s. It contains 317 questions that require the test taker to respond "like," "indifferent," or "dislike" to a variety of occupations, activities, school subjects, and types of people; to indicate preferences between paired options (such as dealing with things vs. dealing with people); and to mark "yes," "no," or "?" to a series of self-descriptive statements.

The SII was developed on the basis of over 60 years of experience with earlier versions of the test and continues the tradition of a counseling instrument that over the years has been used in thousands of research studies and has been given to millions of people. The test must be computer scored, and scores reflect 6 General Occupational Themes, 25 Basic Interests, 211 Occupations (102 occupations separately normed for men and women, plus 7 occupations with single-sex norms), and 4 Personal Styles. Although all people take the same test, separate male and female norms are applied because sex difference in interest patterns frequently occur.

The purpose of the SII is to provide information to the person and professional counselor or personnel officer to aid in academic and career decision making. Scores reflect the person's interests, rather than abilities. The occupational scales compare the person's responses on items known to discriminate between people in the career and men or women in general. For example, the male score for accountant is based on items that have been empirically demonstrated to differentiate between male accountants and men in general. People who choose careers consistent with their interests have been shown to stay with their career choices longer than people who enter careers inconsistent with their interests.

The SII is widely accepted by academic and career counselors as one of the best and most useful tests available for this purpose. It should be used and interpreted in conjunction with trained counselors.

STROOP EFFECT

The Phenomenon

Since psychology's earliest days, we have known that the time to name objects or their properties is considerably longer than the time to read the corresponding words. Cattell (1886) demonstrated this in his dissertation: Saying "horse" to a picture of a horse or "blue" to a color patch took more time than did reading the word *horse* or *blue.* Cattell attributed this difference to the automaticity of word reading, developed through extensive practice.

Fifty years later, John Ridley Stroop combined these two dimensions into a single task (1935/1992; for a biographical sketch, see MacLeod, 1991b). In his dissertation, Stroop printed words in incongruent colors (e.g., the word *red* in blue ink). Asked to read the word and ignore the color, people had little difficulty relative to a control condition where all words appeared in normal black ink. However, asked to name the ink color and ignore the word, people were extraordinarily slow and error-prone relative to a control condition of color patches without words.

This difficulty in ignoring incongruent color words while color naming has come to be called the Stroop effect, or Stroop interference. Following Cattell's lead, the effect is seen as resulting from word reading being so automated that it cannot be prevented even when it disrupts performance. As the gold-standard measure of attention, this effect is one of the largest and most stable phenomena in cognitive psychology, having served as a fundamental tool in hundreds of investigations (for a review, see MacLeod, 1991a). As evidence of its impact, many other analogous interference situations have emerged over the years; Figure 1 illustrates a few of these.

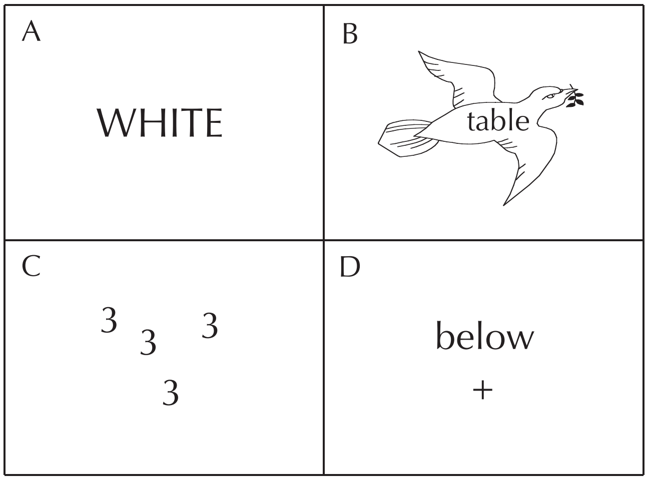

Figure 1. Variations of the Stroop effect. Panel A is the classic task, in which one must name the print color of the word, ignoring the word itself (i.e., say "black"). Panel B is the most frequently studied variant, in which one must name the picture, ignoring the word printed on it (i.e., say "bird"). In Panel C, the task is to count the number of characters, ignoring their identity (i.e., say "four"); in Panel D, the task is to indicate where the word appears with respect to the fixation cross (i.e., say "above"). All panels represent the case that produces interference relative to a control condition.

The Explanations

For many years, the prevalent explanation of Stroop interference was the relative speed of processing account (see Dyer, 1973), in which performance is seen as a kind of horse race in which the wrong horse (the word) beats the right one (the color). This view derives from Cattell's data. More recently, theorists have argued that interference results from people having to execute a controlled process (color naming) in the face of an automatic process (word reading). This explanation derives more from Cattell's theory, and automaticity is viewed as a continuum that develops with practice (MacLeod & Dunbar, 1988).

Most recently, theories have come to emphasize the strength of the connection between particular stimuli and appropriate responses. This is most evident in the new connectionist (neural network) models, notably that of Cohen, Dunbar, and McClelland (1990). Here, a layer of stimulus units (the words and colors) is modulated by task demand units (which set the task as either color naming or word reading). Learning occurs via changing the strength of connections to a layer of intermediate (hidden) units, with the results passed forward to a final output layer containing the responses. Such models do quite well at capturing many crucial findings.

Intriguing Aspects of the Stroop Effect

We now know a great deal about the Stroop effect and the factors that influence it. Clearly, differential practice on the two dimensions is crucial. However, this does not mean that differential speed of processing the two dimensions is the mechanism, as shown by studies that have presented the color information well before the word, thereby giving color a head start, yet have found no reverse interference of color on word reading (Glaser & Glaser, 1982). Indeed, the idea of automaticity has not gone unchallenged either, given that undermining the likelihood of reading the word, such as by coloring only a single letter (Besner, Stolz, & Boutilier, 1997), reduces the effect.

The Stroop task is now widely used as a benchmark measure of attention and automaticity and often appears on standardized tests and in experiments outside cognitive psychology. It's important to note that the effects on the color naming of words are not restricted to color words, but can occur for noncolor words if they are primed by prior presentation (e.g., Warren, 1972). This has led to numerous priming studies, most notably the recent work on the emotional Stroop effect (for a review, see Williams, Mathews, & MacLeod, 1996). Here, time to name the print colors of noncolor words is greater for words related to an individual's

anxiety (e.g., *web* for a person with a spider phobia; *exam* for a test-anxious person) than for neutral words (e.g., *chair*), presumably due to chronic priming. The emotional Stroop effect is now used as a diagnostic tool for the existence of and the successful treatment of anxiety disorders.

In addition, new brain imaging techniques that permit localization of cognitive activity, such as positron-emission tomography (PET) and functional magnetic resonance imaging (fMRI), have also been applied to the Stroop effect, with converging results. Like many other attentional tasks, the Stroop effect shows activity in the anterior cingulated cortex, one of the brain centers associated with cognition, and particularly with attention (e.g., Carter, Mintun, & Cohen, 1995; see MacLeod & MacDonald, 2000, for a review).

Overall, then, this seemingly simple demonstration task that has been with us for over 65 years continues to be very fruitful in our exploration of how attention, a fundamental aspect of human cognition, works. We can expect it to be put to continuing creative use in the exploration of cognition and cognitive neuroscience.

STRUCTURAL PLASTICITY AND MEMORY

Several structural changes in the basic-wiring diagram of the brain have been related to memory storage. These include alterations in the number and pattern of synaptic connections (Moser, 1999), translocation of polyribosomal aggregates to the synaptic spines (Weiler, Hawrylak, & Greenough, 1995), and complex changes in the shape and size of synaptic contact zone (Rusakov et al., 1997). The search for neuronal proteins whose expression correlates with synaptic remodeling has led to the discovery of the growth-associated protein GAP-43, also termed B-50, F1, pp46, and neuromodulin. GAP-43 is a presynaptic membrane phosphoprotein that plays a key role in guiding the growth of axons and modulating the formation of new connections. Neuroplasticity events such as axonal regeneration following nerve injury (Benowitz, Rodriguez, & Neve, 1990) and changes in synaptic efficacy elicited by long-term potentiation (LTP; Meberg, Gall, & Routtenberg, 1993), which is thought to underlie certain forms of learning and memory, determine an increase in GAP-43 expression. Basal values of GAP-43 protein, determined by quantitative immunohistochemistry in selected rat brain regions (Figure 1), are age-dependent. The highest levels of GAP-43 can be found in the adult rat and considerably lower levels in aged rats (Figures 2 and 3). The decrease of GAP-43 content in 31-month-old rats (aged) as compared to that in 18-month-old rats (adult) was statistically significant in hippocampal dentate gyrus (–54%), cingulate cortex (–42%), and olfactory bulb (–38%; see Figure 2). These latter regions of the rat brain exhibit a high degree of plasticity in adulthood but are severely impaired during aging, whereas the other regions investigated (viz., CA1 and cerebellar cortex) maintain a constant, though scarce, capacity of sustaining synaptic remodeling throughout life. The age-dependent decrease of the neuron density innervating the regions that showed this marked loss in GAP-43 immunoreactivity is of particular interest in the analysis of these findings. Hilar hippocampal neurons and cortical neurons providing the bulk of innervation to the inner molecular layer of dentate gyrus and to the cingolate cortex, respectively, show a 20% to 30% decrease in aged (as compared to adult) rats (Coleman & Flood, 1987). The primary neurons of the olfactory epithelium sending afferents to the nerve fiber layer in the olfactory bulb show a striking

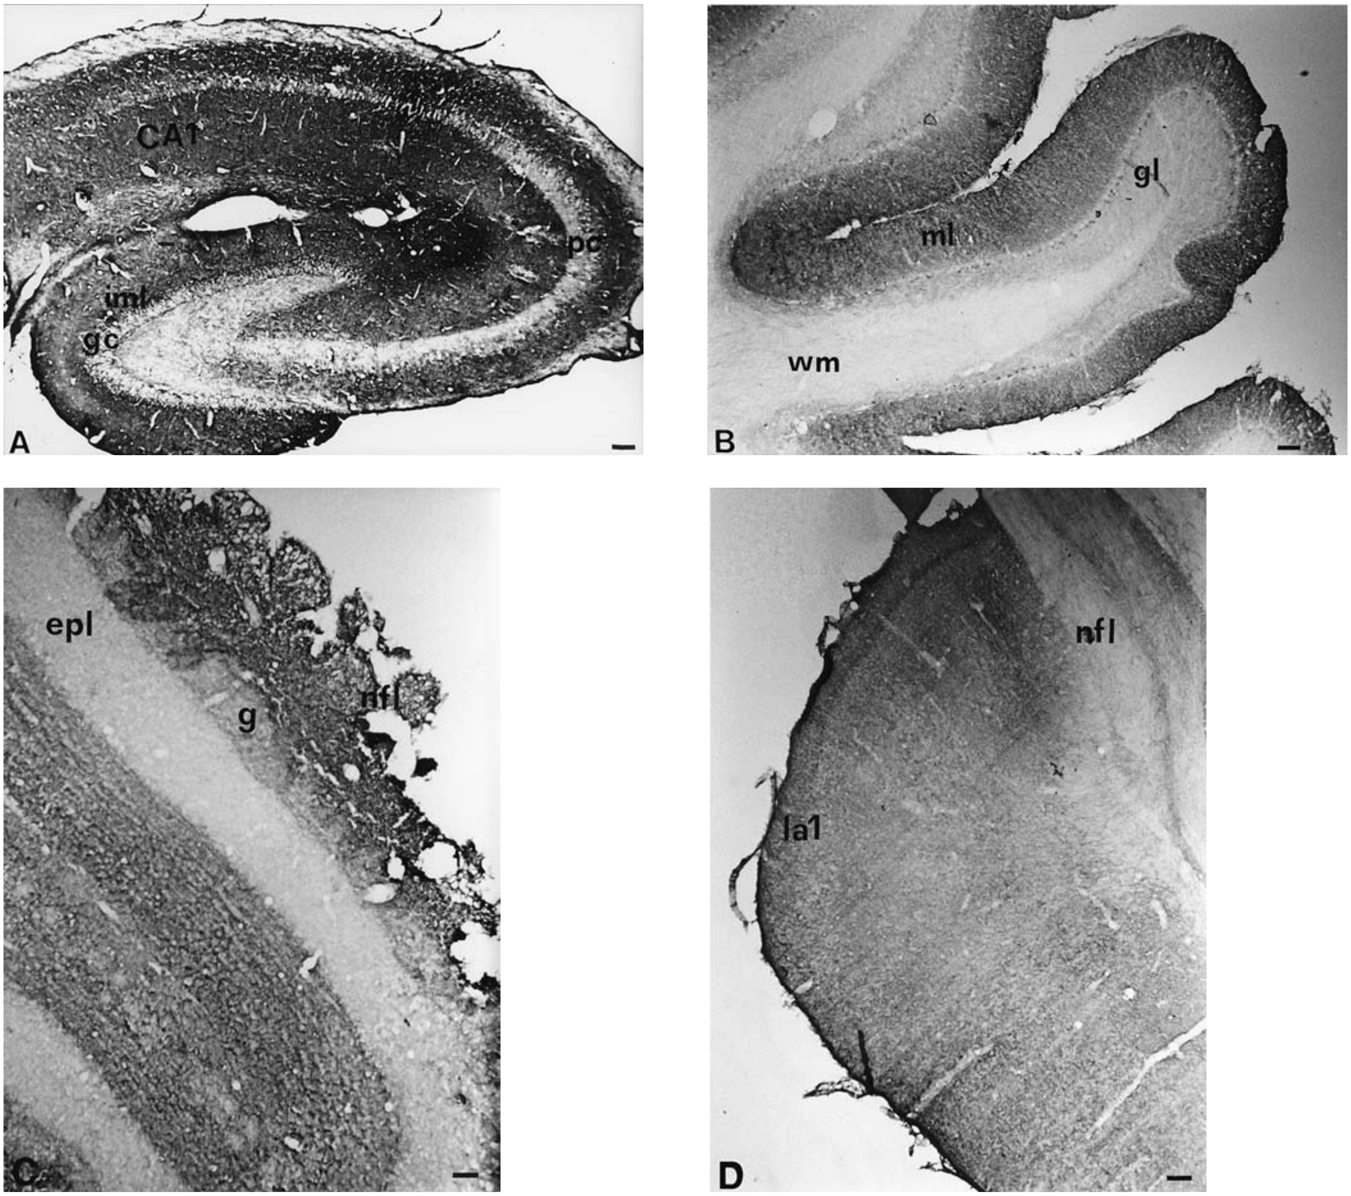

Figure 1. GAP-43 distribution in different brain regions. A: coronal section of ventral hippocampus; neuronal cell soma within the piramidal (pc) and granular layers (gc) are unlabeled while a moderately dense staining is present in the CA1 stratum radiatum (CA1) and in the inner third of the dentate gyrus molecular layer (iml). B: cerebellar cortex; labeling is intense in the molecular layer (ml), lighter in the granule layer (gl) and in the white matter. C: portion of the olfactory bulb; the staining is virtually absent in the external plexiform layer (epl), moderate in the glomeruli (g), and intense in the nerve fiber layer (nfl). D: cingulated cortex. Dense immunolabeling is present in Layer 1 (la1). The underlying neuropil layers are lightly stained. Bars: A, B, and D = 100 μm; C = 300 μm.

decrease in the aged rat, reaching a 48% reduction compared to that in the adult (Hinds & McNelly, 1981). The issues discussed previously indicate that at least two regions showing high levels of GAP-43 in the adult rat brain—namely, the inner molecular layer of the dentate gyrus and Layer 1 of the cingulated cortex—significantly decrease their ability to sustain synaptic turnover during aging. It has been demonstrated that the hippocampus is involved in memory acquisition and consolidation (Shephard, 1988b), whereas the cingulated cortex is reported to be a center for the expression of emotional behavior (Shephard, 1988a). Both these functions are markedly altered in elderly subjects (Timiras, 1994).

STRUCTURALISM

As a school or system of psychology, structuralism had its antecedents in British philosophy of the eighteenth and nineteenth centuries. John Locke had established the empirical tradition by stating that all knowledge came from experience, and the mind at birth was a tabula rasa (blank tablet). Locke opposed the continental philosophers, such as René Descartes, who claimed that some ideas were inborn.

Structuralism began formally with the teachings and writings of Wilhelm Maximillian Wundt (1832–1920) in the late nineteenth century. Historians of psychology generally agree that Wundt founded the first psychological laboratory in 1879 in Leipzig. Many important experiments were performed in Wundt's laboratory: reaction time, color mixing, afterimages, psychophysics, and word associations. Wundt's interpretation of the nature of psychology became the first psychological system or framework within which one could organize the facts and theories of psychology.

At the turn of the century, many young pioneers in psychology came to study with Wundt at the University of Leipzig—among them Hall, Cattell, and Titchener. Edward Bradford Titchener (1862–1927) took Wundt's psychology to the United States, where he named the system *structuralism.* He modified and enlarged Wundt's basic tenets and headed the experimental laboratory at Cornell University.

Both Wundt and Titchener defined psychology as the study of consciousness or conscious experience. This kind of knowledge was dependent on the experiencing individual as opposed to experience independent of the individual, which was the subject matter of physics and chemistry. This definition focused psychology on human experience. Throughout the first three decades of the twentieth century, structuralism was a dominant school in American psychology. By the early 1930s, however, the system was beginning to decline in popularity.

For Titchener, there were three classes of elements of experience: sensations, feelings, and images. The elements of sensation came from the various senses: vision, hearing, taste, smell, touch, the muscular sense, and various organic senses. For Wundt, feelings—the inner experience—had three dimensions: pleasantness-unpleasantness, excitement-calm, and strain-relaxation. Titchener proposed only the pleasantness-unpleasantness dimension, stating that Wundt's other dimensions could be reduced to actual sensations. The images that constituted the third class of elements were like weak sensations. Titchener concluded that there were a total of 43,415 different sensory experiences.

Titchener also believed that these elements had dimensions of attributes. There was *intensity,* which referred to how strong or weak the sensations were. *Quality* referred to the kind of experience, as in a particular pitch or tone. *Duration* referred to how long the experience lasted. *Clarity* involved the place an experience had in consciousness. Those experiences at the focus of consciousness would be very clear, whereas those at the fringe would be vague. Finally, Titchener described the attribute of *extensity* or volume, which he believed applied only to visual experience.

Attention referred to the arrangement of conscious elements. It could be voluntary, as when one intentionally directs one's attention to a particular object. Habitual attention was developed with repetition, as when a mother attends regularly to the signals from her child. Finally, involuntary attention could be exemplified by a sudden flash of lightning or a clap of thunder.

In experience, the elements were combined. The means by which this combination could occur was *association.* This was the so-called glue that held the elements together. Titchener and Wundt borrowed the laws of association from the tradition of the British empiricists and associationists.

Both Wundt and Titchener had distinguished the two worlds of experience: the mental (consciousness) and the physical. The relationship between these two worlds could be explained through psychophysical parallelism. For instance, the experience of a particular color had its parallel in the length of light wave, or an experience of a certain pitch had its parallel in the frequency of the sound wave.

One aspect of experience that Wundt failed to explain was the meaning of a particular idea or set of experiences. Therefore, Titchener constructed his context theory of meaning. Here meaning was divided into core and context.

The methodology of structuralism was introspection and experimentation. Introspection was of special importance in analyzing experiences. Titchener maintained that science was dependent on observation and that introspection was one of the methods. In his *Outline of Psychology,* Titchener laid down certain rules for the introspectionist to follow: (1) One must be unbiased; (2) one must have complete control and not allow one's attention to wander; (3) one's body and mind must be fresh and not fatigued or exhausted; and (4) one must feel well, be of good temper, and be interested in the experience being introspected. Titchener warned against the stimulus error, which constituted a reading into the experience of associations from one's past that would contaminate the raw experience.

Structuralism no longer exists as a systematic position. It was very much limited to what psychologists could study in their minds; it had no applications. In 1933 Edwin Boring, a student of Titchener at Cornell, wrote *The Physical Dimensions of Consciousness,* in which he tried to correlate the attributes of consciousness with characteristics of impulses going along the sensory nerves to the brain. Intensity supposedly correlated with the rapidity of the impulse and quality with a patterning of the impulses, but this was purely hypothetical.

What is left of structuralism is to be found in various aspects of sensory psychology, but in a way, structuralism fulfilled its purpose. It set psychology out as a discipline separate from philosophy with a methodology of investigation at least in part experimental. Introspection, as a method, was subjective and qualitative. As psychology was being directed toward a broader scope, to include behavior of both animals and humans, along with applications to the world outside the laboratory, structuralism was eclipsed.

STRUCTURED AND SEMISTRUCTURED CLINICAL INTERVIEWS

The past few decades have witnessed a shift among clinical psychologists and psychiatrists toward the increased use of a more formal clinical interview process. It has become commonplace to categorize clinical interviews, based on the degree of structure imposed by the interviewer, into one of three

subtypes: structured, semistructured, and unstructured. The unstructured interview is characterized by the clinician's refraining from the use of prescripted queries or a predetermined order of content coverage (Shea, 1990; Wiens, 1990). In direct contrast, a structured interview comprises predetermined questions presented in a predefined order, with tightly operationalized criteria used for interpretation (Beutler, 1995). Semistructured interviews are something of a hybrid case. Like structured interviews, they consist of predetermined questions presented in a predefined order; however, following the predetermined questions, the interviewer is free to follow up as necessary to obtain sufficient information.

Semistructured interviewing, like structured interviewing, is concerned with obtaining sufficient information for reliable and valid rating with respect to some particular content domain (e.g., diagnostic category, symptom severity, level of function, etc.). It differs only in that it allows clinicians more latitude to formulate queries in making a rating. Accordingly, the present chapter subsumes both semistructured and structured interviews under the rubric of the structured interview.

The Shift from Unstructured to Structured Interviews

The increasing use of structured interviews may be traced to the confluence of several historical developments. In the 1960s and 1970s there was growing recognition that the traditional method of diagnosis (i.e., the unstandardized, unstructured interview) was highly unreliable (see Hersen & Bellack, 1988). Structured interviews thereby became an invaluable means of assessing each disorder within the *Diagnostic and Statistical Manual of Mental Disorder* third edition (*DSM-III;* American Psychiatric Association, 1980) in a systematic fashion (Shea, 1990). Another development has been the recent increase in the influence of managed care organizations (MCOs). MCOs, by virtue of concerns for cost containment, have provided an impetus for the widespread use of structured interviews, inasmuch as such interviews allow more valid and accurate diagnosis with minimal prerequisite clinician training (Wiens, 1990).

The Structured Interview: Advantages and Disadvantages

There are several advantages in comparison with unstructured interviewing. Due to their explicit use of operationalized criteria, structured interviews facilitate higher levels of interrater reliability than do unstructured interviews (Segal, 1997; Segal & Falk, 1998). Standardization in administration decreases the amount of both criterion and information variance (Segal, 1997; Segal & Falk, 1998). Structured interviews also attenuate the need for clinical judgment and permit the clinician to rely on operationalized criteria and interpretation based on normative values. In addition, two different interviewers utilizing the same interview are less likely to elicit discrepant information due to differences in interviewing techniques. Due principally to its superior reliability and validity, structured interviewing is now the accepted gold standard of *DSM*-based diagnostic assessment. Descriptions of the most commonly employed structured interviews are listed in Table 1.

Another advantage is that administration and interpretation of the interviews requires less training than for unstructured interviews. Nonetheless, they do require a considerable amount of specialized training, not only because the initial training in interview administration is extensive, but also because retraining is necessary to prevent interviewer drift.

Structured interviews are also capable of providing information tailored to the researcher's or clinician's needs. For example, the relevant sections of a structured interview may be employed to elicit information to address a specific referral question or diagnostic issue. Alternatively, for a more thorough intake assessment, an omnibus diagnostic interview may be employed to screen a patient across the entire spectrum of disorders.

There are a few notable limitations with structured interviews. They constrain an interviewer's freedom in exploring relevant issues to suit the needs of the client (Beutler, 1995). For example, clients may not reveal information unless they are comfortable with the interviewer; thus, questions that are not tailored to the needs of the patient or that proceed in a forced manner may actually result in the patient's revealing less information or being untruthful (Scheiber, 1994; Sullivan, 1954). Finally, clinicians who employ structured interviews lack flexibility in exploring their clinical intuitions when interviewing (Beutler, 1995).

Structured Interviewing: Clinical Considerations

Despite the limited amount of free time available during a structured interview, the clinician is faced with the need to establish rapport quickly with the client in order to obtain accurate and complete information (Beutler, 1995; Scheiber, 1994). Beutler (1995) recommended that the clinician "ensure that the desired expectation and mind set are developed by the patient" (p. 99) by interviewing in a quiet, protected area to provide a relaxing therapeutic milieu of safety and collaboration. In addition, the clinician can, with the skillful use of nonverbal communication (e.g., body posture, etc.), convey a sense of empathy and positive regard throughout the process. Finally, the interviewer will do well to provide the client beforehand with information (e.g., interview format, etc.) that gives the individual some sense of control during the interview process (Beutler, 1995). With such considerations in mind when administering an SI, the clinician can often ascertain important clinical information while simultaneously establishing a positive clinical alliance for subsequent assessment or intervention procedures.

Table 1. Commonly Employed Structured Diagnostic Interviews

Name	Description	Psychometric Properties	Strengths	Limitations
Structured Clinical Interview for *DSM-IV* (SCID; First et al., 1995)	Semistructured; patient and nopatient versions; specified modules; assesses Axis I disorders	kappa = .72–.84 (Williams et al., 1992)	Length based on need; computer scoring	Limited Likert scale; moderate training
Schedule for Affective Disorders and Schizophrenia (Endicott & Spitzer, 1978)	Semistructured; based on Research Diagnostic Criteria for Axis I disorders; specified modules	ICC = .84–1.00 (Endicott & Spitzer, 1978); kappa = .63–1.00 (Spitzer et al., 1979)	Assesses past and present psychopathology	Limited Likert scale; no reliable computer scoring; reliance on clinical judgment; extensive training
Diagnostic Interview Schedule (Robins et al., 1981)	Structured; investigation of mental illness in general population; assesses Axis I disorders	kappa = .60–.80 (Robins et al., 1981)	Designed for nonprofessionals; 1-hour administration; computer scoring	Closed-ended questions; dichotomous scoring with no clarification; assesses only symptoms
International Personality Disorder Examination (Loranger et al., 1994)	Semistructured; specified modules; assesses Axis II disorders based on *DSM* and ICD-10 criteria	kappa = .51–.87; stability = .52 (Loranger et al., 1994)	Uses 5-year inclusion rule; requests examples for scoring	Limited Likert scale; requires extensive training and clinical judgment; 2–3 hour administration
Structured Clinical Interview for *DSM-IV* (SCID-II; First et al., 1994)	Semistructured; screening questionnaire available; specified modules; assesses Axis II disorders	kappa = .48–.98 (Maffei et al., 1997)	Screening component; open-ended follow-up questions	Limited Likert scale; questions grouped together by disorder; extensive training and clinical judgment required

Note: Information on instrument strengths and limitations is abstracted from Segal and Falk (1998).

STRUCTURED CLINICAL INTERVIEW FOR DIAGNOSIS

Since the 1970s, the perception of the low reliability of psychiatric diagnosis and the need for homogeneous research groups have stimulated the improvement of classification systems of psychiatric disorders. The establishment of specific diagnostic criteria for each mental disorder, with inclusion and exclusion criteria, as well as criteria for evaluation of severity and duration of symptoms, significantly enhanced the reliability of psychiatric diagnosis.

Nevertheless, the refinement of operational diagnostic criteria fails to control other sources of low reliability, such as the interviewer's behavior and expectations and variations in the information obtained from the patient. To overcome these difficulties, structured and semistructured interview instruments have been developed, based on different classification systems. The development of these instruments is intermingled with the development of the classification systems on which they are based. The instruments began to play an important role not only in research but also in clinical practice and in the training of mental health professionals.

One of the first structured interviews was the Present State Examination (PSE), which aimed at describing psychopathological phenomena in a reliable and objective way (Wing, 1983). The PSE consists of 140 items, 107 referring to symptoms described by the patient and 33 referring to behavior observed by the interviewer. It includes a glossary with comprehensive and precise definitions of each item, the evaluation of which depends on knowledge of psychopathology, clinical judgment, and training with the instrument. The PSE results in a psychological profile that allows clinical diagnoses through the Catego computer program. These diagnoses are based on a conceptual framework strongly influenced by classical psychopathology and are not comparable to any other diagnostic classification system.

The structured clinical interviews are made of closed-ended questions and can also be conducted by lay interviewers after specific training. Rating depends exclusively on the answer given by the person interviewed, and the interview is usually brief. Examples of this kind of interview are the National Institute of Mental Health's Diagnostic Interview Schedule (DIS) and the Composite International Diagnostic Interview (CIDI). The DIS (Robins, Helzer, Croughan, & Ratcliff, 1981) was developed as part of a large epidemiological study performed in the United States (NIMH-ECA), and it is based on three classification systems. Answers to the questions are codified, and the final diagnosis is established from an analysis made by a specific computer program. The CIDI (Robins et al., 1988) was elaborated for epidemiological studies as well, and its questions are modified items from the DIS and PSE.

Interview instruments such as the Schedule for Affective Disorders and Schizophrenia (SADS) and the Structured Clinical Interview for the *DSM-IV* (SCID) can be classified as semistructured interviews because their open-ended questions allow some flexibility. These features of semistructured interviews require familiarization with the diagnostic criteria of the system on which the interview is based and training in the instrument. Because rating is based on clinical judgment and not only on the answer given by the interviewee, only mental health professionals should apply these instruments.

The SADS (Endicott & Spitzer, 1978) aims at the identification of the 25 diagnostic categories. Reliability coefficients obtained with SADS were significant for the majority of the disorders studied and were better than those for most of the reports available at the time of their publication.

Although SADS has been well accepted, it had some limitations because it does not include all mental disorders and it gives little attention to psychosocial assessment. Due to these shortcomings, the SCID was published in the 1980s; it has the same outline of SADS but is based on criteria and diagnostic categories proposed by the American Psychiatric Association (*DSM-III-R* and *DSM-IV;* APA, 1994).

The SCID (Spitzer, Williams, Gibbon, & First, 1992) can be applied to patients as well as to individuals not identified as patients. The interviewer is encouraged to use all sources of information available. Questions are grouped according to diagnosis or criterion, and the scores and diagnostic criteria are integrated into the structure of the interview so that several hypotheses are successively tested. When an essential diagnostic criterion of a particular disorder is not fulfilled, remaining questions on the disorder may be ignored.

The SCID begins with an overview session, which follows the general process of a nonstructured clinical interview. From this overview, the interview is organized in modules that generally refer to the diagnostic classes of the *DSM-IV.* This organization allows the evaluation of a few modules only. Studies of SCID reliability have generally yielded satisfactory results.

The good reliability indexes obtained with these instruments have enabled studies with more precise information about the clinical picture, evolution, prognosis, and comorbidity of several mental disorders. Nevertheless, the use of structured and semistructured clinical interviews relies on familiarization with the instrument. For this purpose, adequate training with the instruments is fundamental and should follow the instructions provided by the instruments themselves.

STUDY METHODS

Outside the classroom, the primary means by which students learn have long been the preparation of homework assignments, other guided-study activities monitored by a teacher, and independent study on special projects. The requisite studying typically involves reading and remembering written materials, drilling on exercises so as to master specific skills, and preparing and presenting materials for evaluation by a teacher. In addition to textbooks, students often use library resources to acquire specialized information from printed reference materials or from audiovisual sources. Most studying involves working alone, although students often join together to clarify and plan assigned study activities, to obtain feedback or help on assignments, to review completed homework material, or to review for an upcoming examination. Studying traditionally has required a wide variety of activities. The advent of new educational technology based on televised and computer-assisted instruction likely will bring about changes in these traditional study approaches.

Observers have noted wide variations in the study methods typically employed by students. The time and place for studying, the physical conditions of the study environment, and the employment of specific study mechanics were some of the many factors observed. In spite of the lack of consistency seen, a large number of how-to-study books, guides, and tests have been published to assist students in improving study skills. Many schools and colleges offer study skills instruction.

Robinson, originator of the SQ3R method for reading textbooks, presented the approach following several years of research on the reading problems encountered by failing, average, and superior students. This study method, or some variation of it, has been included in most how-to-study books published subsequently. Five steps comprise the SQ3R method:

1. *Survey* the chapter.
2. *Question* by turning headings into questions to be answered while reading.
3. *Read* actively by underlining key phrases and marking main points.
4. *Recite* the main points to yourself in your own words to check your learning.
5. *Review* periodically to refresh your memory and ensure retention.

Pauk developed the five-step Cornell system for taking notes as the product of extensive trial and experiment based on learning theory. The steps are as follows:

1. During the lecture, *record* as many meaningful facts and ideas as possible in the main column of the notes.
2. After the lecture, *reduce* these ideas and facts into key words and phrases listed in the recall column.
3. Cover the main column and *recite* the main facts and ideas to yourself using the cues provided by the recall column.
4. *Reflect* on the material and write your own ideas and opinions in a separately organized summation.

5. Periodically *review* the notes quickly to ensure that the material is remembered.

Brown and Holtzman employed direct observation, interviews, and questionnaires to develop the Survey of Study Habits and Attitudes (SSHA). Specific suggestions for implementing efficient study skills and effective academic attitudes were derived directly from the SSHA.

Many how-to-study guides and study skills inventories have been published, but there appears to be considerable disagreement as to what constitutes good study habits. Some researchers have turned to the investigation of motivational factors. Following an intensive review of existing how-to-study literature, Brown concluded that attitudinal and motivational characteristics were of potentially greater importance than the purely mechanical procedures of studying. More important was what motivated the student to acquire or not acquire, and to use or not use, methods for effective studying.

The following topics are included in most study skills courses: using time efficiently, developing concentration skills, organizing the study area, reading and marking textbooks, skimming articles, summarizing concepts, organizing and outlining material, improving remembering, building vocabulary, taking lecture notes, taking reading notes, setting meaningful goals, conducting library research, writing in-class themes, writing topic reports, studying mathematical material, studying scientific material, preparing laboratory reports, making oral reports, reviewing for examinations, desensitizing test anxiety, taking objective tests, writing essay examinations, and taking problem tests.

Beginning in the early 1960s, the rapid expansion in educational opportunities for the economically disadvantaged resulted in the admission of large numbers of nontraditional students who were relatively ill-prepared for the academic demands of higher education. Without effective assistance in acquiring needed learning skills, these students found that the open door to educational opportunity quickly became a revolving door to academic oblivion. Concern about their low level of academic preparedness led to the creation of special learning centers with programs designed to help these students acquire the learning skills necessary for academic success.

Since its introduction, the concept of a college-wide learning assistance center to provide broad-based services for all students appears to have been widely accepted. Fiscally, however, the movement is struggling for full administrative recognition and acceptance. In the future, the development and implementation of new educational technologies, including computer-based instructional systems, should further expand the role and scope of learning assistance activities in both secondary and higher education.

SUBLIMINAL INFLUENCE

Subliminal influence is defined as the use of persuasion tactics delivered below the threshold of awareness. Although the term *subliminal perception* is well defined in the psychological literature, the term *subliminal influence* is used to refer to a grab bag of techniques ranging from flashing words quickly onto a movie screen, to backward phrases in rock music, to cleverly hidden images in advertisements (see Pratkanis, 1992).

Scientific research has consistently failed to support claims for the effectiveness of subliminal persuasion. In general, researchers have found that people can minimally process subliminal messages (e.g., extracting meaning from a single word presented outside of awareness) but cannot process complex subliminal messages (Greenwald, 1992; Pratkanis & Greenwald, 1988). Regardless of the level of processing, subliminal messages have not been shown to influence behavior.

Opinion polls show that most Americans believe that subliminal messages can influence behavior (Synodinos, 1988). Much of this belief in subliminal persuasion has been stimulated by sensational claims that have appeared in the mass media.

For example, in the late 1950s, James Vicary, an advertising expert, circulated a story claiming that he had secretly flashed the words “Eat Popcorn” and “Drink Coke” onto a movie screen. Vicary claimed an increase in Coke sales of 18% and a rise in popcorn sales of almost 58%. In the 1970s Wilson Bryan Key (1973) proclaimed that subliminal implants were routinely placed in print advertisements. Also in the 1970s, parents and ministers began to evidence concern that rock music contained backward messages often of a Satanic nature. In the 1990s manufacturers of subliminal self-help tapes claimed that their tapes could change personality and behavior. In 1990 the rock band Judas Priest was placed on trial for allegedly putting the subliminal implant “Do it” in one of their songs, causing the suicide deaths of two teenage boys.

Given public belief, it is useful to ask, How effective are subliminal messages in changing and motivating behavior? The conclusion from over 100 years of research is that subliminal messages are incapable of influencing behavior. In a comprehensive review of the literature, Moore (1982) concluded, “There is no empirical documentation for stronger subliminal effects, such as inducing particular behaviors or changing motivation. Moreover, such a notion is contradicted by a substantial amount of research and is incompatible with experimentally based conceptions of information processing, learning, and motivation.” Other reviewers have reached the same conclusion, noting that proclaimed subliminal effects often fail to replicate and that studies claiming to find subliminal influence are methodological flawed and unsound (see Eich & Hyman, 1991; Pratkanis & Greenwald, 1988).

Consider Vicary’s claim for increased sales of popcorn

and Coke because of subliminal messages. In 1958 the Canadian Broadcast Corporation conducted a replication of this study by flashing the message "Phone Now" during a popular television show ("Phone Now," 1958). Telephone usage did not go up during the period. Later, Vicary admitted, "Worse than the timing, though, was the fact that we hadn't done any research, except what was needed for filing for a patent" (Danzig, 1962).

Key's work has been criticized on methodological grounds. For example, Key (1973) reported a study in which 62% of students who saw a Gilbey Gin ad that supposedly contained the word sex embedded in ice cubes reported feeling aroused and sensuous. However, Key did not include a control group (students who saw a similar ad without the implant), and thus we cannot know if these feelings were aroused because of the alleged implant, in spite of it, or for some other reason.

Vokey and Read (1985) conducted an extensive program of research showing that backward messages are ineffective in altering behavior. They found that subjects could not distinguish between backward nursery rhymes, Christian, satanic, pornographic, or advertising messages.

Several studies have investigated the efficacy of subliminal self-help audiotapes. For example, Pratkanis, Eskenazi, and Greenwald (1994) had participants listen to subliminal self-help tapes designed to improve either self-esteem or memory. Some participants received mislabeled tapes—a memory-improving tape labeled as a self-esteem tape and vice versa. After five weeks of listening, the results showed no improvement in self-esteem or memory abilities. To date there have been nine independent investigations of subliminal self-help tapes—all failing to find an effect consistent with manufacturers' claims (see Pratkanis, 1992).

In the trial of Judas Priest, Judge Jerry Carr Whitehead ruled in favor of the band. His ruling stands as a summary judgment of the power of subliminal persuasion: "The scientific research presented does not establish that subliminal stimuli, even if perceived, may precipitate conduct of this magnitude (i.e., suicide deaths)."

SUBLIMINAL PERCEPTION

Beginning with the end of the 1950s, a great deal of public concern was expressed when it was claimed that a method existed for presenting advertising messages that could influence behavior at an unconscious level. A typical example might be at a movie theatre, where the message "Buy popcorn" could be given during the film, and even though viewers were not consciously aware of its presence, they might still be motivated to purchase popcorn. The procedures involved quickly flashing messages on the screen at a size, speed, or brightness that was too insignificant to produce conscious awareness. Such stimuli are called *subliminal,* from the Latin for below (*sub*) the threshold for consciousness (*limen*). Subliminal perception comes about when such stimuli, even though apparently unnoticed, appear to exert an effect on later behavior.

There is still controversy as to whether subliminal stimuli have the ability to persuade in advertising settings. Many researchers note that stimuli that are intended to be subliminal may occasionally make it into our consciousness. It has often been suggested that it is only on those occasions when the stimulus actually is detected (even if these are statistically rare) that the message can have any effect. Thus, to persuade people to any great extent, the message cannot be truly subliminal but has to reach consciousness, at least occasionally (e.g., Smith & Rogers, 1994).

The problem with the study of subliminal perception was that it caught the attention of the popular media, and many of the claims made for subliminal persuasion were extravagant and bizarre. For instance, there were claims that people were being manipulated through subliminal sexual symbolism, which was hidden in television and even magazine advertisements. Strange stories were published in

which it was suggested that teenagers were being deliberately exposed to subliminal stimuli in musical recordings, which were placed there by revolutionaries and terrorists who wanted to stir aggressive responses in them. Some religious groups claimed that subliminal messages in films, television, and musical recordings were being used by devil worshippers to undermine the morals of the public and to gain them new converts. Such suggestions could never be convincingly substantiated, however these apparent associations with fringe groups and marginalized social activities, plus a lot of bad science, brought the whole topic into disrepute for many years.

Over the years three lines of research have rehabilitated the study of subliminal perception. These are based on what is called the mere exposure effect (Zajonc, 2002). This is a phenomenon that demonstrates that simple repeated exposure to a stimulus, even if it is not consciously noticed or attended to, can produce positive feelings for that stimulus when it is later encountered. This effect has proven to be a robust, reliable phenomenon, showing that people tend to prefer stimuli that they have seen before, no matter what they are—whether drawings, photographs, nonsense words, or even social behaviors of people. One important aspect of these findings is that the effect seems to be quite primitive. People do not need to be consciously aware that they have seen the stimulus, nor do they have to be able to remember ever encountering it before. In fact, a number of studies have suggested that the emotional effect associated with mere exposure is even greater if the stimuli are subliminal (e.g., Bornstein & D'Agonstino, 1992).

Clinical psychologists have cited another aspect of how emotional factors play a role in subliminal perception. This is in the case of perceptual defense. Typical examples occur in experiments in which observers are briefly shown nonsense syllables or figures and are asked to identify them. If some of the stimuli presented had been previously associated with painful electric shock, they might now be expected to be somewhat anxiety producing. In general, it is found that such negative emotional stimuli are recognized less readily than are neutral stimuli—as if the observers are defending themselves from the painful memories evoked by seeing such stimuli. Still, it is possible to show that perception has taken place subliminally. This is done through the use of physiological measures of anxiety, such as the galvanic skin response, which registers the person's negative emotional state for the stimuli, even though the observer cannot consciously identify them. This process, in which there is an emotional response but no conscious awareness of the stimulus, is sometimes also called *subception.*

The most recent, and probably the most active, lines of research involving subliminal perception have involved cognitive psychologists. They have returned to this process due to their interest in an effect called *priming,* in which the occurrence of one stimulus may make it easier to perceive a later stimulus that is related to it in some way. For example, a priming study involving word recognition might first briefly present the prime word, which is followed by a complex *masking stimulus* that prevents the prime word from being consciously seen, followed by a target word. Thus we might briefly present the word "nurse" and follow it with a semantically related word (one that has an associated meaning) such as "doctor" or an unrelated word such as "carrot." Typically, priming is shown when the person responds more quickly to the related word than to the neutral word. It is believed that the prime word has somehow activated cognitive processes associated with the first stimulus, making the stimuli that come later easier to process (see Neely, 1991). The label *priming* comes from the fact that older water pumps often needed to be primed by first having some water poured into the pump chamber before they could efficiently draw additional fluid up from the well.

One of the interesting aspects of priming is that the priming stimulus does not have to be conscious, but can be totally unconscious or subliminal (e.g., Klinger & Greenwald, 1995). During the course of such research, it has become clear that subliminal perception may actually trigger associations that are necessary for us to read quickly and process written information efficiently. Thus we register data from the words that are still ahead of us on the printed page subliminally. Our unconscious perception of this material makes it easier for us to recognize those words and ideas when we encounter them later, as our eyes move down the text, because these associations have already been subliminally primed (Sereno & Rayner, 1992). This suggests that subliminal perception is not a rare psychological oddity but may be a common and integral component in the way that we process information from our environment.

SUCCESSIVE APPROXIMATION (SHAPING)

The terms *successive approximation* and *shaping* are shorthand for the phrase "successive reinforcement of closer and closer approximations to the target behavior" (Skinner, 1953). This procedure is distinct from other operant reinforcement methods (e.g., chaining) in that it relies on both reinforcement and extinction applied to a changing set of criteria responses (Galbicka, 1994). The target, or terminal, response is either infrequent or novel to the organism (i.e., has never been performed), limiting the utility of direct reinforcement of the response. Shaping, as the name implies, involves slow transformations of the organism's behavior over time, much like the process of shaping clay into a fine piece of pottery. Initially, a gross or distal response is sufficient for the delivery of reinforcement. In time, a more similar response is required. This process continues until only the terminal response elicits reinforcement.

Shaping is a powerful tool for expanding the repertoire of organisms, including humans. Shaping may be intentional or unintentional, depending on whether the behavior was produced from planned or accidental reinforcement (i.e., contrived vs. natural consequences).

Examples

1. *Planned shaping.* Molly would like to teach her 1-year-old daughter Sally to call her mommy. Sally currently does not say mommy, but she does say "ma" occasionally. Molly begins to pay extra attention (e.g., says "Great job, Sally" and smiles) when Sally says "ma." Soon Sally says "ma" often. Molly decides it is now time for Sally to say something more similar to mommy, so she no longer praises her for simply saying "ma." Instead, Molly reinforces Sally for saying "ma" twice in a row, which sounds like "moma." This process continues until moma is shaped into mommy.
2. *Accidental shaping.* Timmy is a 3-year-old boy without a history of tantrums. Timmy is bored with shopping at the store, and he begins to whine. His father Don tries to console him by picking him up, talking to him, and giving him something with which to play. The next time Timmy is bored while shopping, he begins to whine. Don appears to have accidentally reinforced Timmy's whining in similar situations. However, whining is no longer sufficient to get Don's attention (i.e., extinction). Timmy changes his whining to wailing, which does catch Don's attention (i.e., extinction burst). Now Don tries to console him as he did before. This process continues, and each time Timmy's behavior escalates in order to gain his father's attention. Ultimately, Timmy tantrums to gain the attention of his father. Hence, Don inadvertently shaped this tantrumming response in Timmy.

Considerations

Although shaping may be accidental, programmed shaping may be of more use to clinicians, parents, and teachers. To shape behavior successfully, Martin and Pear (1999) indicated four factors to be considered.

1. *Specifying the final desired behavior.* The final desired behavior, or terminal behavior, should be well specified. This includes topography (shape or form), intensity, frequency, context, and antecedent conditions. By defining the target behavior with this level of clarity, caretakers and providers will be more likely to apply the shaping procedure consistently.
2. *Choosing the starting behavior.* The starting behavior must occur at a rate likely to receive reinforcement during the training session. This necessity will help select the starting behavior from among the class of possible starting behaviors, even if other behaviors more closely resemble or approximate the target behavior. For example, Molly might have mistakenly chosen to start with Sally saying "mommy," a word not yet within her repertoire.
3. *Choosing the shaping steps.* Prior to shaping, one should consider the likely permutations between the starting behavior and the terminal behavior. Because complex behavior is comprised of multiple chains or patterns of response, the possible permutations may be limitless. Nonetheless, decisions regarding which approximations are sufficient to qualify as progress toward the target behavior must be made. The exact rules for this process are not well specified in the literature. Typically, the new criterion should result in reinforcer delivery at least 50% but not more than 80% of the time. A rate less than 50% is likely to result in an effect similar to extinction of variable ratio schedules, whereby the behavior slowly varies and then tapers off. This is sometimes also referred to as ratio strain. A rate higher than 80% is likely to create inflexibility when the next criterion for success is initiated.
4. *Moving along at the correct pace.* Shaping protocols are typically flexible; if the organism fails to display the new approximation response, simpler steps may be created to facilitate learning. Likewise, when progress is more rapid than expected, criteria for reinforcement may be raised (i.e., more advanced steps may be attempted).

Additional Considerations

In addition to the four typical considerations, it is also important to consider selecting reinforcers, tracking progress, and choosing target behaviors.

- *Selecting reinforcers.* Often overlooked in discussions of shaping, reinforcer selection may be the most important

consideration in shaping. Rewards are not the same as reinforcers; reinforcers by definition increase the probability of occurrence of the preceding behavior. Have the person help choose the reinforcer, if possible. Then monitor the shaping process to see if the response frequency is increasing. If it is not, you are not using a reinforcer.

- *Tracking progress.* Progress is not a given in behavioral psychology. Data need be collected to evaluate progress. Data are needed to determine reinforcer effectiveness, pacing of steps, and strength of new responses. A graph of the data employing a changing-criterion design will help consolidate most aspects of the shaping program into a single, simple form.
- *Choosing target behaviors.* Shaping is a highly effective tool for teaching new behavior. Shaping may be used to change behavior even when the organism, or person, is unaware that it is being shaped. Careful consideration should be taken when deciding to use shaping, and target behaviors must be appropriate and beneficial for the organism. Take the time to consider the ethics of your decision, and involve the participant in this process if applicable.

SUICIDAL BEHAVIOR AMONG YOUTH

Epidemiology

Adolescent suicide completions and attempts are public health problems (U.S. Department of Health and Human Services, 2001). Although suicide is uncommon in childhood, it is the fourth leading cause of death in 10- to 14-year-olds and the third leading cause of death for adolescents ages 15–19 (www.cdc.gov). The suicide rate for young people has tripled since 1950, and among adolescents the rate has stabilized at 11 suicides per 100,000 (Goldsmith, Pellmar, Kleinman, & Bunney, 2002). Firearms, hanging, and suffocation are the most common means for suicide completions in youth (www.cdc.gov). Within a 12-month period, approximately 20% of adolescents in the United States seriously consider attempting suicide; 16% develop a suicide plan; 8% attempt suicide; and 3% attempt suicide in a manner requiring emergency medical attention (Centers for Disease Control and Prevention [CDC], 1998b, 2000).

Suicidal ideation and attempts are more common among adolescent females than males (CDC, 1998b). However, completions are more common in boys than girls (5:1; National Center for Health Statistics, 2000). Although historically, suicide rates have been lower among African American than Caucasian youth, the gap has narrowed recently (CDC, 1998a). The highest youth suicide rate is among Native American males (Wallace, Calhoun, Poweel, O'Neil, & James, 1996). Latino youth do not appear to be overrepresented among completed suicides.

Risk Factors

Genetic and Biological

A family history of suicidal behavior increases the risk of attempted and completed suicide (Glowinski et al., 2001; Gould & Kramer, 2001). The role of genetic factors is further supported by twin and adoption studies (Roy, 1992). Early studies on the link between serotonin abnormalities and suicidal behavior in youth suggest an association similar to that reported among adults (Gould & Kramer, 2001).

Psychopathology

A major psychological risk factor for youth suicide and suicide attempts is a history of a prior suicide attempt (Gould & Kramer, 2001). Psychiatric disorders found to be risk factors for the continuum of suicidal behavior include mood, anxiety, disruptive behavior, substance use, and personality disorders (Borowsky, Ireland, & Resnick, 2001; Esposito & Clum, 2002; Zimmerman & Asnis, 1995). A history of prior mental health care is often noted in youth who attempt suicide (Stewart, Manion, Davidson, & Cloutier, 2001).

Cognitive Factors

Cognitive factors associated with suicidal behavior among youth include low self-esteem, hopelessness, negative automatic thoughts, maladaptive attributional styles, and external locus of control (Nock & Kazdin, 2002; Wagner, Rouleau, & Joiner, 2000; Yang & Clum, 2000).

Stressful Life Events

Early negative life events are associated with later suicidality in youth (Yang & Clum, 2000). Adolescent suicide attempters report higher rates of stressful life events 12 months prior to the attempt (Davidson & Linnoila, 1991). Specific life stresses include fights with parents, breakups with a romantic partner, loss of a parent due to death or divorce, and legal or disciplinary problems (Gould & Kramer, 2001).

Family

Parental psychopathology is associated with suicidal ideation, attempts, and completions in youth (Gould & Kramer, 2001). Changes in the composition of the family, such as death, parental separation, divorce, or other losses, also put adolescents at increased risk for suicidal behavior (Gould & Kramer, 2001; Wagner, 1997). The experience of physical or sexual abuse is a risk factor that has been replicated across several studies (Wagner, 1997). Other family risk factors include poor family or parent-child communication, parent-child discord, family aggression, and low family cohesiveness (Gould & Kramer, 2001; Wagner, 1997).

Peer Relationships

Suicidal youth tend to evince impaired social skills, poor interpersonal relationships, and deficient problem-solving skills, making them vulnerable to engaging in suicidal behavior in response to negative stressors (Yang & Clum, 1994). Perceived peer rejection and the lack of close friendship support serve as risk factors for suicidal ideation and attempts (Prinstein, Boergers, Spirito, Little, & Grapentine, 2000). Lifetime prevalence rates of physical and sexual dating violence are associated with suicidality (Sileverman, Raj, Mucci, & Hathaway, 2001). Further, a burgeoning literature reveals that same-sex romantic attachments and relationships increase an adolescent's risk for suicidal behavior (Borowsky et al., 2001). Gay adolescents are two to three times more likely to attempt or commit suicide than are their heterosexual peers (Radkowsky & Siegel, 1997).

Imitation and Contagion

Direct or indirect exposure to suicide is associated with suicidal behavior among youth (Spirito, Brown, Overholser, & Fitz, 1989). Person-to-person contact with another individual who has attempted suicide is linked with suicidal behavior (Borowsky et al., 2001). Indirect exposure to suicide, through media coverage of suicide attempts or fictional accounts of suicide, also is linked with suicidal behavior among adolescents (Gould, 2001). Furthermore, the intensity of media coverage of suicides of well-known celebrities is positively related to suicidal behavior.

Socioenvironmental Factors

Difficulties in school and school absence pose suicide risks for youth (Gould & Kramer, 2001). To date, limited data are available on the effects of socioeconomic status on suicidal behavior in youth.

Protective Factors

Data from the National Longitudinal Study of Adolescent Health revealed that perceived parent and family connectedness were protective against suicide attempts for adolescent males and females across racial-ethnic groups (Borowsky et al., 2001). Emotional well-being was found to be a protective factor for females, and high grade point average was a protective factor for males (Borowsky et al., 2001). The endorsement of more reasons for living protects youth from attempting to kill themselves (Gutierrez, Osman, Kopper, & Barrios, 2000).

Assessment

Berman and Jobes (1991) stressed the importance of a multifocused assessment of suicidality and outlined six dimensions: imminent risk, lethality and intent, predisposing conditions and precipitating factors, psychopathology, cooperation with the interviewer, and coping skills and resources. Using these data, the clinician may screen for levels of risk of suicidal behavior. More recently, the American Academy of Child and Adolescent Psychiatry (AACAP, 2001) presented practice parameters for the assessment of suicide ideators and attempters that underscore the importance of evaluating the suicidal behavior, assessing underlying conditions and risk factors, and determining the risk for death or repetition. The practice guidelines note that such assessment may include the use of specialized suicide scales and instruments that tap related constructs and risk factors.

Crisis Management and Intervention

Management of a suicidal youth is focused on keeping the individual physically safe and alive until the crisis has passed. Optimally, there is a service delivery system that includes emergency room interventions, inpatient services, and short- and long-term outpatient services available for youth who attempt to kill themselves (AACAP, 2001; Rotheram-Borus, Piancentini, et al., 1996; Rotheram-Borus, Walker, & Ferns, 1996; Spirito, Boergers, Donaldson, Bishop, & Lewander, 2002).

Cognitive-behavioral, interpersonal, dialectical-behavior, psychodynamic, family systems, and integrationist approaches may be applied to suicidal youth (AACAP, 2001). Cognitive-behavioral treatment is structured and focuses on building interpersonal, coping, and problem-solving skills. Empirical data suggest that cognitive-behavioral strategies that increase coping skills are useful in decreasing suicidal ideation and suicide attempts (Rotheram-Borus, Piancentini, Miller, Graae, & Castro-Blanco, 1994; Rudd & Joiner, 1998). Dialectical-behavior therapy with suicidal adolescents with a diagnosis of borderline personality disorder appears to be associated with reduced rates of psychiatric hospitalization (Miller, Rathus, Linehan, Wetzler, & Leigh, 1997). A time-limited, home-based family intervention has been found to be helpful for those suicidal youth who also are depressed (Harrington et al., 1998). Further, developmental group psychotherapy, which combines problem-solving, cognitive-behavioral, dialectical-behavior,

and psychodynamic group psychotherapy approaches, was found to be more effective than routine care in reducing suicidal behavior and behavioral disorders and enhancing school attendance (Wood, Trainor, Rothwell, Moore, & Harrington, 2001). To date, no clinical trials have ascertained the efficacy of psychopharmacological interventions (AACAP, 2001). Nonetheless, medications may be essential in stabilizing and treating the psychological conditions often observed in suicidal children and adolescents.

Prevention

There has been a proliferation of suicide prevention strategies over the past 10 to 15 years, and there was a recent call to action for the systematic development, evaluation, and implementation of such prevention efforts (U.S. Department of Health and Human Services, 2001). The School Health Policies and Programs Study found that 26% of states required suicide prevention at the elementary school level; 42% required prevention programs at the middle or junior high level; and 46% mandated programs during the senior high school years (www.cdc.gov).

Suicide prevention strategies aim to identify suicidal youth and refer them to intervention programs that target the reduction of risk factors. Several case-finding strategies have been used to increase the recognition and referral of suicidal youth (AACAP 2001; Gould & Kramer, 2001). Case-finding strategies can be accomplished via the provision of school-based suicide awareness curricula, large-scale screening efforts, gatekeeper training, crisis centers and hotlines, media counseling to minimize imitative suicide, and training health care professional to improve the recognition and treatment of mood disorders. Suicide awareness programs aim to facilitate self-disclosure and increase awareness of suicidal behavior among peers so that youth can secure help for their suicidal peers (Hazell & King, 1996). Large-scale screening efforts, which may be conducted in schools, forensic settings, treatment programs, and primary care providers' offices, incorporate self-report and individual interviews in a multistage assessment of risk factors associated with suicide attempts and completions (Shaffer & Craft, 1999). Once these at-risk youth are identified, they may benefit from such youth suicide prevention efforts as Counselors Care (C-CARE) and Coping and Support Training (CAST; Randell, Eggert, & Pike, 2001). The purpose of gatekeeper training is to develop the competence of natural community helpers (e.g., teachers, clergy, and coaches) to identify youth at risk for suicidal behavior and their level of risk and to make appropriate referrals once they identify the young people in need (Kalafat & Elias, 1995). Even though there is limited data on the efficacy of telephone crisis services for youth, hotlines may prove useful if their use were increased and optimized (Gould & Kramer, 2001). Guidelines have been promulgated to support sensible and responsible media coverage of youth suicide by both the Centers for Disease Control and Prevention and the American Foundation for the Prevention of Suicide (AACAP, 2001). Finally, there is some evidence that training for primary care providers on the evaluation of mood disorders and suicidality may be associated with reduced rates of suicidal behavior and more appropriate interventions (Rihmer, Rutz, & Pihlgran, 1995). One final risk-factor reduction strategy that deserves mention relates to the restriction of lethal means, such as the recent efforts at restricting access to firearms, safer prescribing regarding antidepressant medications, and emission controls (Gould & Kramer, 2001).

Postsuicide Intervention

There has been an increase in the number of available school- and community-based postvention programs, programs that target family members, friends, fellow students, and community members following a suicide. Unfortunately, little empirical investigation has been conducted to determine the effectiveness of these programs (Gould & Kramer, 2001). Of course, long-term support and services also need to be easily accessible for families and friends grieved by the loss of a loved one (AACAP, 2001).

SULLIVAN'S INTERPERSONAL THEORY

Interpersonal theory is a theory of interpersonal relations developed by Harry Stack Sullivan largely in the 1930s and 1940s.

Key Concepts

Sullivan emphasized the social aspects of human nature. He defined psychiatry, personality, and key assessment and treatment concepts in interpersonal terms. Performances, or interactions in the interpersonal field, are the means by which disturbances are formed, revealed, and treated. Sullivan also emphasized the crucial role of anxiety in personality formation and disturbance.

The Social Nature of Human Nature

In *Conceptions of Modern Psychiatry,* Sullivan (1953) defined personality as "the relatively enduring pattern of recurrent interpersonal situations which characterize a human life." Even hermits maintain an interpersonal life, through imagery, memory, and fantasy. Dynamisms, which are characteristic patterns of internal or overt social behavior, are the smallest meaningful unit of study of an individual. Dynamisms may involve thinking, feeling, or acting in relation to other people, who need not be present or even real.

That behavior often reflects relationships with persons not actually present was a cornerstone of Sullivan's approach. He perceived the distorting effects of such relationships in the troubled behavior of his patients. The inner aspect of this distortion he called personifications—images one holds of self or others, with their attendant feelings and impulses and ideas. Stereotypes are widely shared personifications, positive or negative. Personifications built up in one relationship may be triggered in another, with consequent distortions of thinking, feeling, and acting, as when a person perceives and relates to an employer as though to an overly critical and demanding parent.

Anxiety

Anxiety can be the most crucial formative influence in the interpersonal field, and its origins are the origins also of personality and of self. Their common roots lie in the helpless nature of infants, who survive only if nurtured. The distressed infant cries. A caregiver responds. The cry becomes a communication within a relationship and the first tool of need reduction. Over time, such interactions acquire two consequences: satisfaction arising from need reduction, and security arising from the preservation of a necessary relationship.

Threats to biological survival bring fear. Threats to security bring anxiety, which may be devastatingly powerful for a being lacking the maturity and experience to manage or dampen it. Given sufficient experience of anxiety, its subsequent avoidance may become the central goal for the infant or young child. Patterns in the interpersonal field have both inner and outer aspects, and the objectively helpless infant may begin to preserve security subjectively through the dynamism of sleep.

The growing dynamism of self (Sullivan's word for the complex of processes that come increasingly to monitor, evaluate, and regulate activities in the interpersonal field) seeks above all else to preserve security. Behaviors bringing approval from significant others are strengthened; behaviors bringing disapproval are inhibited and may be eliminated.

The processes of awareness and behavior control are increasingly bent on preserving security through conforming to the expectations of others. When disapproval attaches to behaviors or events that cannot be managed by the child, however, the child must control the experience rather than the event. When confronted by a threat to security, such as parental disapproval of anger, the child may disown the angry feelings through selectively not paying attention to them and by not giving them labels. Thus, while the anger does not cease to exist, the child ceases being aware of it. Sullivan called this process dissociation. Security is preserved by removing awareness from an undesired aspect of personality, which paradoxically places that aspect beyond the corrective effects of experience and may permit it to continue unmodified into adulthood.

Even more common in the preservation of security are parataxic distortions by which significant aspects of self or others are misperceived, mislabeled, and misunderstood in ways that lessen their anxiety-producing properties. The young child is in prolonged transition from the disconnected jumble of sensory experiences and perceptual impressions characterizing infancy toward a mature mode of rational, logical experience that even adults often fail to maintain. This transitional mode, called the parataxic by Sullivan, is characterized by a primitive associational sense of causality and by developing language use. Still in the process of learning firm and consistent concepts, labels, and meanings, the child's idiosyncratic and personalistic use of language in speech and thought facilitates parataxic distortions. Thus the self, central to each person's understanding of his or her own nature, may become isolated from that nature and therefore from all interpersonal rela-

tions. Mental health is restored through increasing awareness of one's interpersonal relations.

Performances

Children dominated by the preservation of security grow up to have very distorted understandings of their performances in the interpersonal field. The deceptions they practice on themselves are often facilitated by persuading others to perceive them as they wish to be seen or, at the least, by preventing others from seeing them as they fear they might really be. All children go through this. It is the way in which cultures preserve their characteristics. Proscribed patterns are inhibited; desired patterns flourish. When children receive the broad, persistent, and intense disapproval of significant others, however, they become more than conforming: They become emotionally disturbed. They misperceive not only their own performances but also those of others because of personifications built through disturbing interactions with significant others. They readily perceive the characteristics of these personifications and relate more to them than to the people actually present. Such troubled and isolated adults approach interpersonal situations warily and communicate in guarded, defensive, and sometimes bizarre ways as a result of the myriad distortions they superimpose on the actual situation.

Sullivan developed numerous strategies for detecting distortions in interpersonal relations and the often subtle manifestations of anxiety that accompany them and for relating to disturbed people in such a way that they could begin to experience the truths behind the evasions, thus expanding the self. Central to his methods was the conviction that all the therapist can objectively know is performance in interpersonal situations. All else is inference. Even the patient's effort to describe internal experience becomes a performance in the interpersonal field, and its content is therefore suspect. Sullivan perceived the therapist as a participant in the performances of the patient and considered that the data of assessment and treatment arise in this process of participant observation. The psychiatric interview is a special kind of interpersonal relation that demands great skill on the part of the therapist. Sullivan's greatest contributions may lie in his sensitivity to the isolation and anxiety of the disturbed persons he treated, in his broad perspective on the processes giving rise to their human misery, and in the richness of his therapeutic strategies on their behalf.

SURVEYS

Opinion, attitude, and interest surveys are unlike traditional tests in that they are self-report measures in which the persons responding indicate what they feel or think; there are no right or wrong answers. The person responding to the survey is generally asked to rate each item on some type of rating scale—from *most* to *least,* or *strongly agree* to *strongly disagree,* or simply on a scale of anywhere from 3 to 10 points.

The Gallup Poll and the Harris Poll are two of the better-known opinion surveys. Much market research is also of the opinion survey variety.

Attitude surveys are generally used to measure such things as how people feel about social or personal objects or issues. Examples are the Job Attitude Scale and the Attitudes Toward Women Scale.

Interest surveys measure preferences for certain activities; these usually are work-related activities, but some surveys also measure preferences for play or leisure activities, or for activities related to school subjects. Interest surveys are generally used for career and educational exploration and planning. There are two principal types—those with internally built, homogeneous scales; and those with externally, or empirically, built criterion scales. Surveys of the former type are based on clusters of internally related items, with each cluster representing a basic interest dimension, such as outdoor, artistic, mathematical, or literary interest. Examples are the Kuder Preference Record, Vocational; the American College Testing Program Interest Inventory; and the Self-Directed Search. Scores are based on a comparison between the individual's responses and those of a representative sample of people in various grade or age ranges. Criterion, or empirically developed, scales, however, are based on the item responses of people in the criterion group or occupation represented by the scale. Scores represent the degree of similarity with the responses of people in the criterion groups. The validity of an interest survey is generally measured by how well it predicts the occupation or activity a person will enter, or how well satisfied the person will be with that occupation or activity. Empirically developed interest surveys generally are expected to meet an additional requirement: They must be able clearly to discriminate, or distinguish, members of one occupation from members of other occupations. Examples of empirically developed interest surveys are the Kuder Occupational Interest Survey and the Strong-Campbell Interest Inventory.

SYMPATHETIC NERVOUS SYSTEM

The sympathetic nervous system (SNS) is one of two branches of the autonomic nervous system, which controls the function of organs and glands in the body (called the efferent portion) and senses changes in these organ systems (the afferent portion); the other autonomic branch is the parasympathetic nervous system (PNS). The neurons that comprise the efferent SNS arise from the thoracic and lumbar portions of the spinal cord (i.e., the middle of the cord). Thus, this system is sometimes referred to as the thoracolumbar branch. Sympathetic fibers originating from the thoracic cord innervate organs of the head, neck, chest and upper abdomen. Sympathetic fibers originating from the lumbar cord innervate the lower gastrointestinal (GI) tract and other organs of the pelvis.

The anatomy of the efferent autonomic nerves to each organ or gland includes preganglionic neurons, which exit the spinal cord, and postganglionic neurons, which directly innervate the target organ. A ganglion is comprised of the cell bodies of the postganglionic neurons and is the region where the pre- and postganglionic neurons communicate with one another. In the SNS, the preganglionic fibers that exit the spinal cord are typically short, and many of them synapse within a chain of ganglia found just outside the bony vertebral column housing the spinal cord. Other sympathetic preganglionic fibers pass to additional ganglia that do not form part of the sympathetic chain but that are still some distance from the target organ or gland. Typically, then, the postganglionic fibers of the SNS are relatively long since they extend from a ganglion distant from the target organ. The neurotransmitter released by the axon terminals of the preganglionic neurons is acetylcholine. Acetylcholine acts on cholinergic receptors of the nicotinic subtype, which are found on the postganglionic neurons. The neurotransmitter released by the postganglionic neurons onto the target organ or gland is typically norepinephrine, with one exception, the sweat glands, where the sympathetic nerves release mostly acetylcholine with only a small, possible contribution by neurons containing norepinephrine. Afferent autonomic fibers from organs to the central nervous system run alongside the same nerves carrying efferent autonomic fibers. The visceral (i.e., organ) afferents comprise a relatively small proportion of the total number of fibers, less than 20% in some sympathetic nerves. Afferent autonomic fibers provide sensory information about the state of an organ, such as stretch of the bladder, and also relay pain signals. It has been hypothesized that the sympathetic afferents relay mostly pain information and play only a minimal role in visceral sensations needed for bodily regulation (e.g., signals from the GI tract indicating that food is present and needs to be digested).

The organs and glands controlled by the efferent SNS typically receive input from both branches of the autonomic nervous system, a phenomenon referred to as dual innervation. When organs receive innervation from both autonomic branches, the activity in the two branches often produces opposite effects on the organ. For example, the heart rate is controlled by both autonomic branches. Increased activity in the sympathetic branch increases heart rate, whereas decreased activity decreases heart rate. Conversely, increased activity in the parasympathetic branch decreases heart rate, and decreased activity increases heart rate. Thus, each of the two branches is capable of bidirectionally influencing the rate at which the heart beats. A notable exception to the general rule of dual innervation is the sweat glands, which are innervated only by the SNS.

When the body is physically active or engaged in taxing mental activities, the organs of the body tend to mobilize and use resources in a process called catabolism. Often during such states, activity in the SNS is relatively high compared to periods when the organism is resting quietly. For example, during mental distress or engagement, or when there are high levels of bodily activity, the body has an immediate need for more energy. For example, increased sympathetic activation enhances blood flow to muscles needed to perform work by increasing heart rate and shunting blood from areas of low immediate need such as the GI tract to areas of high need like the exercising muscles. Once the immediate metabolic need has been met, activation of the sympathetic system tends to decline at the same time that activation of the parasympathetic system tends to increase. Most of the time, the autonomic nervous system operates somewhere between these extremes of low and high energy mobilization. In these cases, SNS effects on the organs and glands will be intermediate and tuned to the specific needs of each organ system. Thus, even in a person at rest, ongoing sympathetic activity helps to maintain a resting level of tone (i.e., constriction) on the arteries supplying skeletal muscle.

In addition to the tendency for the two autonomic branches to operate in a reciprocal fashion under extremes of activity or inactivity, the two autonomic branches can operate independently. Thus, although a typical pattern of autonomic control consists of the activation of one autonomic branch accompanied by a decrease in activity in the other branch (a reciprocal pattern), this is not the only pattern of response that can occur. The two autonomic branches can have uncoupled effects on a target organ with either increased or decreased activity in one autonomic branch in the absence of any change in activity in the other branch. Alternatively, the two branches can exert coactivational effects where there are simultaneous increases or decreases in activity in both autonomic branches. The existence of nonreciprocal patterns means that one cannot measure function in one autonomic branch and on that basis alone infer the activation level in the other branch.

SYNAPTIC COMPETITION

Synapses converging onto a neuron or muscle fiber compete with each other for control of the electrical excitation of the target cell. In a process driven by the relative activity patterns of the individual synapses and the postsynaptic cell, the efficacy of some synapses is strengthened whereas other synapses are weakened or eliminated altogether. Synaptic competition allows for an experience-dependent editing of neuronal circuits both during development and in the mature nervous system.

Synaptic Competition During Development: Activity-Dependent Refinement of Neuronal Connections

During development, mechanisms of synaptic competition and synapse elimination refine initially established projection patterns. This process allows for input-specific modification of an innate, genetically programmed neuronal circuitry.

At the developing neuromuscular junction, synaptic competition ensures that twitch muscle fibers are innervated by a single motoneuron only. All muscle fibers initially receive inputs from multiple motoneurons that are comparable in synaptic strength. In a competitive process between inputs that is marked by gradual decrease of synaptic strength and loss of muscle fiber surface area covered by synapses of losing inputs, inputs of all but one motoneuron eventually retract. This process appears to depend on the unequal or asynchronous neuronal activity of the convergent inputs, suggesting that the myocyte somehow compares the relative activity of motoneuron inputs and acts to weaken undesired while strengthening desired synapses.

The interplay between the genetically programmed initial establishment and later activity-dependent refinement of connections has been extensively studied in the development of topological and functional organization of sensory afferents to the neocortex, such as the projections from the lateral geniculate nucleus of the thalamus to the primary visual cortex. In the mature nervous system, these afferents to Layer 4 of the cortex are segregated into eye-specific columns, so-called ocular dominance columns. Thorsten Wiesel and David Hubel (1963) observed that, following deprivation of vision in one eye during a critical developmental period, ocular dominance columns from the nondeprived eye expanded at the expense of columns from the deprived eye and visual cortical neurons received inputs mostly from the nondeprived eye. Recent evidence suggests that the formation of ocular dominance columns occurs before the onset of vision and is itself not a consequence of synaptic competition (Crowley & Katz, 2002). Nevertheless, these experiments demonstrate the critical influence of activity-dependent synaptic competition on the modification of ocular dominance in the primary visual cortex and illustrate the functional refinement of thalamocortical connections during development.

Synaptic Competition in the Adult: Plasticity of Cortical Maps and Memory

Even in adults, cortical representations of sensory input are by no means fixed entities but are continuously modified by experience. Michael Merzenich and coworkers have documented the role of activity-dependent competition in the plasticity of topographic maps in the somatosensory cortex (Jenkins et al., 1990; see also Buonomano & Murzenich, 1998). Deafferentation of an area results in an expansion of neighboring receptive regions into that area, increasing the cortical representation of the body surface neighboring that whose cortical input has been ablated. Similarly, increased sensory stimulation of a region leads to an expansion of its representation in the somatosensory cortical map. Analogous sensory experience–evoked changes have been observed in the primary visual and auditory cortical areas.

The hypothesis that synaptic competition and the resulting activity-dependent changes in synaptic strength also underlie learning and memory has captivated many neuroscientists for the past five decades. The psychologist Donald Hebb postulated in 1949 that associative memory has its cellular basis in a persistent strengthening of synapses of a presynaptic neuron onto a postsynaptic neuron, if the former repetitively takes part in firing the latter. Tim Bliss and Terje Lømo (1973) provided an experimental correlate to this postulate when they discovered a long-term potentiation (LTP; on the order of hours to days) of hippocampal dentate gyrus granule cell responses to perforant path stimulation after tetanic stimulation of that projection. LTP, and its counterpart, long-term depression (LTD), have since been observed at synapses in many brain regions. Abundant, albeit circumstantial evidence suggests that synaptic competition and plasticity are the fundamental cellular mechanisms of learning and memory. For instance, memory formation relies on many of the same molecular requirements as synaptic plasticity. Furthermore, experimental manipulation of synaptic plasticity in awake

animals also modulates the ability to acquire memories (see Martin et al., 2000 for a review).

Cellular Mechanisms Underlying Synaptic Competition

The cellular and molecular mechanisms of synaptic competition are likely to depend on the molecular composition of the synapses involved. The mechanism of synaptic competition at a major class of glutamatergic synapses in the central nervous system has received much attention. Reminiscent of Hebb's postulate, LTP at these synapses is produced when presynaptic firing repeatedly precedes postsynaptic firing by a short time span (10–15 ms). Conversely, LTD is produced when postsynaptic firing repeatedly occurs shortly before presynaptic firing. This spike timing–dependent plasticity (STDP) allows for a bidirectional modulation of synaptic strength in the competition between cartels of coordinately active synapses. It has several mechanistic features: (1) Action potentials, initiated in the axon-initial segment, back-propagate into the dendritic tree. (2) Detection of the temporal order of pre- and postsynaptic activation relies on the activation of calcium conductances, such as the ligand- and voltage-gated NMDA-type glutamate receptor. (3) The local calcium concentration, thought to be a nonlinear function of time and membrane depolarization, activates varying sets of signaling cascades. (4) These signals may lead to a relocalization of AMPA-type glutamate receptors or a modulation of their conductance that causes an immediate change in synaptic strength. (5) The long-lasting maintenance of these changes may require alterations of gene expression and/or structural changes including the establishment of new and the elimination of old synaptic contacts (Sjostrom and Nelson, 2000).

SYSTEMS AND THEORIES

In American psychology, systems and theories historically have been closely associated. For this reason it is important that students of psychology know at least the essence of the major systems that have influenced and, to a lesser degree, continue to influence psychological thought.

Systems

A system of psychology may be defined as "an organization and interpretation of . . . data and theories . . . with special assumptions (postulates), definitions, and methodological biases."

The systems that have been most influential in American psychology are generally agreed to be structuralism, functionalism, behaviorism, Gestalt psychology, and psychoanalysis. The first two are now mainly of historical significance, although the role of a continuing kind of diffuse functionalism is noted in the following.

Structuralism

Structuralism was primarily the product of Wilhelm Wundt, who is credited with establishing the first formal psychological laboratory. Its American form was almost single-handedly shaped by Titchener. Wundt and Titchener conceived of psychology as a kind of mental chemistry. Their objective was to analyze conscious experience into its components using a highly refined form of introspection.

Functionalism

Functionalism developed essentially as a protest against the inadequacies of structuralism. Its theme was that all sorts of behavior, along with the conscious experience analyzed by the structuralists, should be grist for the psychologist's mill.

Although clearly anticipated by William James, functionalism as a formal system was founded by John Dewey and James Angell. The system espoused such diverse conceptual and practical efforts as Darwinian evolutionary theory and the mental testing movement. The common el-

ement that bound these diverse interests together was their function—their role in determining both behavior and conscious experience, the two subject matters of psychology.

Behaviorism

The most colorful and influential figure in the development of systematic psychology during the early twentieth century in the United States was John B. Watson, the outspoken founder of the behavioristic system. He developed the position that all that psychology has to study is behavior. During the latter half of the twentieth century, B. F. Skinner replaced Watson as the focus of attention, both positive and negative. Like Watson, Skinner initially worked with animal subjects. His systematic behaviorism was implemented in *operant conditioning,* which stressed emitted behavior rather than the elicited behavior involved in Pavlovian, or classical, conditioning. Also like Watson, Skinner was concerned with practical applications; the best known of these is *behavior modification,* a clinical technique that ignores internal states of the organism and focuses on changes in behavior.

Gestalt Psychology

Gestalt psychology was founded by Max Wertheimer and his two junior colleagues, Wolfgang Kohler and Kurt Koffka. The basic theme was that naive and unsophisticated perceptual experiences should be taken as givens—that is, accepted as they are—rather than reduced to any presumed elements. Phrased differently, the basic and now familiar proposition was that the whole is more than the sum of its parts.

Psychoanalysis

Sigmund Freud's enormously provocative psychoanalytic system left enduring marks on psychology as well as on many other disciplines. Although psychologists differ widely in their evaluation of psychoanalysis, there can be little doubt that Freud's contributions have greatly enriched our understanding of human behavior. The impact of psychoanalysis, with its stress on early development and largely, if not wholly, unconscious sexuality as determinants of neurosis and psychosis, has been greatest on clinical psychology.

Theories

A theory may be defined as an attempt to explain some set of empirical events, particularly when assumptions are made as to how to bridge gaps in available knowledge about underlying factors. Theories vary widely in their organization and scope, from the simplest of hunches, through hypotheses of various sorts that deal with specific empirical predictions, to large-scale systems of deductively related laws. The role of the more informal theorizing is in special need of emphasis because of the much greater attention typically paid to the formal types of theory.

The term *model* has come to serve as a kind of synonym for theory. In its original usage, model referred to an explanatory effort that was based on some better supported explanatory framework in another discipline, such as the use of a mathematical formulation as a basis for deriving experimental tests in psychology.

Deductive theory is characterized by the derivation of propositions, to be tested empirically, on the basis of logically related prior premises.

Inductive theory operates in exactly an opposite manner. It allows disparate bits and pieces of data to accumulate and to be gradually articulated into theoretical propositions without any explicit guidance (in its ideal form at least).

Functional theory attempts to remedy the major faults of deductive and inductive theories. It proceeds cautiously with respect to the empirical basis from which it is generated, but at the same time it is explicitly guided.

T

TARDIVE DYSKINESIA

Tardive dyskinesia (TD) is the most troublesome and feared extrapyramidal side effect (EPS) of long-term conventional antipsychotic drug therapy. Tardive dyskinesia has been defined as an extrapyramidal hyperkinetic movement disorder characterized by involuntary, repetitive, and irregular abnormal movements, present for a minimum of 4 weeks and occurring after a minimum of 3 months of cumulative classical antipsychotic drug (i.e., neuroleptic [NL]) exposure (Kane et al., 1992).

The presence of TD has been related to poor treatment compliance and, due to its associated stigma, to an important deterioration in quality of life. Even though TD is often not severe and may even improve in a significant proportion of cases (Gardos et al., 1994), the severe, disabling, progressive, and irreversible cases (even though a minority) constitute a permanent threat in long-term antipsychotic or NL treatment because it is still not possible to predict either who is going to develop TD or of what type or severity (Larach, Zamboni, Mancini, & Gallardo, 1997).

Epidemiology of Tardive Dyskinesia

The prevalence of TD has been reported to range from 3% to 62%, with a mean prevalence of around 20% and a cumulative incidence of 5% for each year of NL exposure. For patients over 50 years of age, cumulative incidence rises to 50% or more after 3 years of NL exposure. The natural history of TD, as suggested on long-term follow-up studies, tends to have a fluctuating course and an overall trend toward amelioration with time, although some researchers have found chronic persistent dyskinesia in more than half of the patients in long-term follow-up studies (Kane, 1995).

Risk Factors

The best-identified risk factor is age, with patients under the age of 40 years having about a 10% risk of developing TD; this risk increases five- to sevenfold in elderly patients. Gender differences show that the ratio of women to men developing TD is 1.7:1 and that women tend to have more severe TD and more spontaneous dyskinesias. Vulnerability to drug-induced acute and chronic EPS, secondary to disruption of the nigro-striatal system, is of particular concern in children, who are at special risk because of their immature brains. The presence of schizophrenic negative or deficit symptoms, affective disorders, structural brain abnormalities, diabetes mellitus, and smoking have also been identified as risk factors for TD. Whether the use of either depot neuroleptics or concomitant long-term therapy with such drugs as anticholinergics and lithium presents a special risk still remains controversial. The prolonged use of those NL drugs that are not marketed as NL in the treatment of nonpsychotic conditions—drugs that include many antiemetics, various NL-type dyspeptic agents, and some NLs with marked antidepressant effects (e.g., amoxepine)—frequently constitutes the risk of extended NL exposure without the physician's being aware of that risk (Casey, 1995b).

Clinical Features of Tardive Dyskinesia

Clinical features include involuntary, repetitive, and irregular movements affecting different body regions: facial muscles (usually in older adults) involving the lips, jaw, and tongue (bucco-linguo-masticatory dyskinesia), frequently accompanied by involuntary grimacing and spasmodic eyeblinking; and axial musculature and extremities (usually in children and younger patients) involving any type or combination of choreic, athetotic, myoclonic, and dystonic movements. Tardive dyskinesia usually includes other tardive EPS features such as tardive dystonias and tardive akathisia, considered to be tardive because they also appear after prolonged NL exposure. Dystonic features convey a more severe and disabling picture. As with all extrapyramidal syndromes, movements disappear during sleep and worsen with stress.

The severity and complexity of the movements in TD impair motor functions and psychosocial interaction and produce subjective discomfort symptoms. Motor feature impairment can involve difficulties with speech or swallowing; inability to wear dentures; ulcerations of the mouth mucosae; impairment for daily routines such as walking, sitting, and standing; and significant progressive weight loss that may become a life-threatening condition. These impairments produce different levels of psychological distress that range from no awareness of discomfort to different levels of embarrassment, desperation, and hopelessness, and even to suicidal ideation and behavior (Casey, 1995a).

Early detection of TD may be possible by observing mild and poorly defined movements such as grimacing or facial tics (especially of the eyes and lips); chewing or other bucal movements; mild and fine vermicular movements of the tongue; and rocking and limb restlessness in the absence of the subjective discomfort of akathisia.

Differential Diagnosis

The psychotic motor features of schizophrenia, such as stereotypies, mannerisms, and bizarre postures, should first be ruled out. Other hyperkinetic idiopathic syndromes, such as some rarely spontaneous dyskinesias observed in psychotic patients never exposed to NLs, or others such as senile dyskinesias and Meige's and Tourette's syndromes, should be considered. Secondary dyskinesias caused by systemic diseases such as lupus erythematosus, Sydenham's chorea, Henoch-Schonlein's purpura, chorea gravidium, hyperthyroidism, and hypoparathyroidism, and by hereditary diseases such as Huntington's and Wilson's diseases, should be sorted out. Brain lesions caused by cerebrovascular accidents, tumors, and brain chemical poisoning must also be regarded, as should postencephalitic dyskinesias. Other drug treatments that may produce reversible and irreversible dyskinesias, such as amphetamines, tricyclic antidepressants, antihistamines, phenytoin, oral contraceptives, and L-dopa (in the treatment of Parkinson's disease) should be considered as causes (Casey, 1995b).

Pathophysiology

The pathophysiology of TD remains unknown because there have been no consistent, demonstrable abnormalities found in neurochemical and postmortem receptor studies. The DA nigro-striatal pathways would be functionally abnormal through mechanisms related to the increase in the number of DA receptors secondary to prolonged DA receptor blockade, changes in sensitivity, and poorly understood pre- and postsynaptic DA receptor interactions. High liability for acute EPS seems to be related to increased TD risk. The difficulty with NLs or the so-called typical or classical antipsychotics is that their effective antipsychotic dose range produces more than 70% of D2 receptor blockade in the basal ganglia, an amount very close to the dose needed for the appearance of EPS (around 80% D2 receptor blockade; Farde et al., 1992). The prevailing question in this case is whether the DA role is primary or modulatory. The combination of low D2 and high serotonin (5HT2) receptor blockade activity seems to reduce the risk for EPS symptoms by an (as yet) unclarified mechanism. It appears that serotonin receptor blockade probably modulates DA activity by increasing DA in the substantia nigra as well as in the prefrontal area (Meltzer, 1993). The new generation of antipsychotic drugs—the so-called atypical or novel antipsychotics—has been developed based on these blockade strategies to widen the margin between the dose required for the antipsychotic effect and the dose that causes EPS occurrence.

On the other hand, other, even less confirmed neurochemical theories and substrates have been considered: noradrenergic, cholinergic, and GABAergic; neuropeptide dysfunction (cholecystokinin, substance P, neurotensin, somatostatin); disturbances in mineral metabolism (iron); glucose-insulin-NL interaction; neurotoxicity in the basal ganglia due to high oxidative metabolism caused by increased catecholamine turnover; and so on. Such theories have led the way to miscellaneous pharmacological strategies in the treatment of TD; among them, the more widely used benzodiazepines have helped some patients. Treatment with vitamin E (alpha-tocopherol) at high doses has also been tried, with variable clinical results (Casey, 1995c).

Treatment

The treatment of TD remains highly empirical. At present, there is no definite, effective, standard, safe TD treatment, and it is not possible at this time to predict the treatment response to a specific agent. Thus, prevention continues to be the best strategy regarding TD (Gardos & Cole, 1995). The use of first-line atypical antipsychotics (e.g., risperidone, olanzapine, and quetiapine) for the long-term maintenance treatment of schizophrenia and for some forms of severe affective disorders represents in varying degrees the most relevant factor in TD prevention because of the low incidence of EPS associated with these drugs. Clozapine, the best representative agent of the atypical antipsychotics and for which there are virtually no reports of dystonia or definite TD causation, has been reported to be especially effective in ameliorating or resolving roughly 60% of moderate to severe TD with dystonic disabling features (Larach et al., 1997; Lieberman et al., 1991). Its wide and first-line use is limited by the potential of blood dyscrasia and by the necessity of regular blood tests. Treatment of TD with atypical antipsychotics should be maintained long enough to avoid rebound and to ensure full therapeutic effect. Ideally, periodic video recording during standard examinations is advisable for long-term follow-up and outcome assessment (Larach et al., 1997). The definite effectiveness of atypical antipsychotics in the treatment of overt TD cases still awaits further testing.

TASK DESIGN

The simplification and standardization of the tasks comprising a job have long been advocated as means of enhancing productivity in organizations (Taylor, 1903). Indeed, these strategies have been shown to lead to simplified production scheduling, lowered training costs, and reduced expenditures for labor through the employment of lower-skilled, more interchangeable, and cheaper workers (cf. Aldag & Brief, 1979). However, simplified and standardized tasks are perceived by job incumbents as monotonous, leading them to feel bored and dissatisfied with their work; in turn, this boredom and dissatisfaction presumably cost employers in terms of increased absenteeism and turnover and reduced production output (Hulin & Blood, 1968).

To counteract these costs, job enlargement (Kilbridge, 1960) and job enrichment (Herzberg, 1968) have been advocated as alternative task-design strategies. Conceptually, however, the two strategies are quite similar and can be thought of as entailing the design of jobs to include a wider variety of tasks and to increase the job incumbent's freedom of pace, responsibility for checking quality, and discretion over method. For the most part, the research addressing the two strategies has taken the form of testimonial evidence; thus, one is unable to assert few, if any, generalizations regarding their efficacy (Aldag & Brief, 1979).

Building on the works of Turner and Lawrence (1965) and Hackman and Lawler (1971), Hackman and Oldham (1975) advanced a model to guide more rigorous research aimed at enhancing both theory and practice. They asserted that through various psychological states, five core dimensions influence job incumbents' affective and behavioral reactions to their jobs. These core dimensions are (1) skill variety—the degree to which a job requires a variety of different activities; (2) task identity—the degree to which the job requires the completion of a whole and identifiable piece of work; (3) task significance—the degree to which the job has a substantial impact on the lives or work of other people; (4) autonomy—the degree to which the job provides substantial freedom, independence, and discretion to the incumbent in scheduling work and in determining the procedures to be used in carrying it out; and (5) feedback—the degree to which carrying out the work activities required by the job results in the incumbent's obtaining direct and clear information about the effectiveness of his or her performance. Critical reviews of the research generated by the Hackman and Oldham model indicate that the core job dimensions are likely to lead to higher levels of job satisfaction on the part of job incumbents but do not appear to influence their behaviors significantly (Aldag, Barr, & Brief, 1981; Roberts & Glick, 1981).

More recently, knowledge enlargement, which involves adding requirements to the job for understanding procedures or rules relating to the organization's products, has been advanced as an alternative to task enlargement. It has been shown to yield more satisfaction as well as less overload and fewer errors (Campion & McClelland, 1993). Additionally, in response to manufacturing-process innovations such as just-in-time inventory control and total quality management, it has been advocated that one consider how worker flexibility and employee learning and development might be encouraged by job design (Parker, Wall, & Jackson, 1997). Thus, greater attention should be focused on the context in which jobs are embedded.

Salancik and Pfeffer's (1978) social information processing model explicitly considers the importance of social context in the subjective construction of job attitudes. For example, the model posits that in the process of forming job perceptions, job incumbents rely on what their coworkers say. However, evidence in support of the model has not been promising. Critical reviews have suggested that greater attention be paid to factors such as the employee's past experiences and susceptibility to influence by others (Zalesny & Ford, 1990).

The question of how to design tasks to enhance employee motivation, and thus productivity, remains open. Clearly, personal experiences and intuition lead one to believe that

the contents of jobs do vary in terms of their motivational potentials. Until that potential is verified empirically and its costs and benefits are compared with those strategies advanced by Taylor's principles of scientific management, a scientific psychology of task design will be more of an aspiration than a reality.

TASTE AVERSION LEARNING

The acquired aversion to a particular food resulting from experience with that food is known as taste aversion learning (TAL), or conditioned taste aversion. The terms *avoidance* and *flavor* may also be used to refer to this effect, yielding synonyms such as flavor aversion learning, conditioned taste avoidance, and so on. Although the process was first elucidated in studies of radiation sickness, TAL is now recognized as an intrinsic behavior that allows vertebrates to learn about toxic foods.

TAL contributes to an animal's ability to limit intake of poisonous food items. It can be thought of as a hardwired system linking the nose and mouth with the gastrointestinal tract and the brain. The brain integrates signals regarding the flavor and physiological effects produced by ingestion of toxic foods. These integrated signals become a memory that helps animals determine which foods are safe to eat and which are not. Without TAL, animals would likely repeatedly eat the same toxic foods.

Learned taste aversions arise from a sequence of events that begin with the ingestion of a food item. Though not required, aversions occur more readily when unfamiliar (novel) foods are ingested. The flavor of the food serves as a cue called the conditioned stimulus (CS). The flavor cue allows the specific food item to be identified when encountered on future occasions. The next, and most important, event in the process is subsequent occurrence of gastrointestinal distress (i.e. nausea or emesis). The pharmacological source of the illness is known as the unconditioned stimulus (UCS) and may be present in the food or delivered separately. For example, both CS (the flavor of the plant) and UCS (the toxin) are ingested when a toxic plant is eaten. Conversely, a cancer patient may eat a particular food (CS) and suffer nausea from radiation treatments (UCS).

Conditioned aversions are formed experimentally by delivering the UCS shortly after the food is consumed. Lithium chloride is commonly used for this purpose. The nausea produced by lithium chloride is rapidly associated with the food. Although aversions can be formed from a single exposure to the UCS, repeated exposures to the UCS may be required to generate persistent aversions. For example, a single UCS exposure can produce an aversion to a novel food item, but multiple exposures are often needed to form aversions to familiar foods. If familiar and novel foods are followed with a single UCS exposure, an aversion will be formed to the novel food.

The mode of action of the UCS is critical to forming aversions. Stimuli that negatively impact the emetic system (like lithium chloride) are required to produce aversions to associated flavor cues. Stimuli that do not produce nausea are less likely to initiate flavor aversions. Learning occurs whether the delay between CS and UCS exposure is a few seconds or many hours.

TAL is an affective (i.e., subconscious) process that does not require cognitive learning. However, cognitive learning may generate aversions to other sensory attributes of the food such as color or texture. This is why poisonous insects often exhibit aposematic warning colors for protection. These visual cues allow the insects to advertise their toxicity without having to be eaten first. Avoidance of a specific

cue may continue even when the UCS is not present. Aversion to a cue in the absence of a consequence produces an effect known as *Batesian mimicry.* Some nonpoisonous insects are called mimics because they have evolved visual cues that mimic the colorations of poisonous insects. The species that possess both CS and UCS are known as models. Mimics are avoided as if they are models because they possess the cue associated with illness.

Because ingestion of a mimic does not produce negative consequences for the consumer, aversion to the cue will be greatly diminished if the mimic is repeatedly eaten. Extinction (complete loss of the aversion) will occur as subjects learn that ingestion of the cue does not produce illness. Extinction occurs rapidly when subjects are forced to ingest items that contain the CS but not the UCS. However, ingestion of the model after extinction may produce spontaneous recovery of the aversion, which may occur months after extinction. Conversely, latent inhibition describes the lack of an aversive response when subjects are exposed to the model following extinction. Latent inhibition is an example of the conflict that occurs when foods thought to be safe suddenly cause illness.

Transfer of avoidance from one food item to another containing a similar cue is known as *generalization.* Generalized cues that closely resemble the CS are most likely to be avoided. In addition to flavors, other sensory cues are subject to generalization. This phenomenon causes animals to assume that all similar foods must also cause illness. However, extinction of generalized aversions will occur if the UCS is not present in the new food that contains the cue.

Even with this learning process in place, animals often ingest toxic plants or prey anyway. Learning processes fail for a variety of reasons. For instance, not all toxins produce the gastrointestinal distress required for learning. Delays between CS ingestion and illness also diminish food aversions. Although delays of many hours do not interfere with learning, delays between ingestion and symptomatic consequences can be several years with some toxins. Learning processes may also fail when the environment changes. Herbivores in unfamiliar environments will ingest familiar toxic plants and avoid unfamiliar nutritious ones, even though illness results from ingestion of poisonous plants.

TAL is a hardwired memory that is formed affectively yet lends itself to further development through cognitive processes. There are several principal aspects of TAL. Namely, it is robust, is highly specific, is acquired rapidly, occurs with a single exposure, and is tolerant of time delay between presentation of CS and onset of UCS effects. These features make it an important mechanism in foraging behavior because animals with this memory need not relearn that certain food items are toxic every time they are encountered.

TASTE PERCEPTION

Sense of Taste

Taste is one of five senses that may be involved in sensory evaluation, each sense being associated with a different type of receptor. The sense of taste is important because of its role in food recognition, selection, and acceptance. The final criteria by which food is judged and wins acceptance relate to sensory properties: How does it look? How does it taste? How does it smell? Individuals use their senses to determine whether a product is edible and whether it pleases them. The first is a judgment, the second a reaction; and the more favorable the reaction, the more likely the product is to be acceptable (Woods, 1998).

Taste Receptors

Taste or gustatory sensations occur with stimulations of chemoreceptors in taste buds on the tongue, soft palate, and throat, the majority being on the tongue. The taste buds are small, oval-shaped protruberances containing two types of cells.

The surface of the tongue is rough because of the presence of papillae, which vary in size and shape. The largest are the circular circumvallate papillae, which contain taste buds, and these papillae form an inverted V shape at the back of the tongue. Fungiform papillae, which are mushroom shaped and also contain taste buds, are located on the tip and at the sides of the tongue (Arvidson, 1979). Moderate numbers of taste buds are present in foliate papillae, which occur in the palate and at the back of the throat. Evidence of anatomical influences on the different sensitivities between individuals has been provided by Miller and Bartoshuk (1991) and Bartoshuk, Duffy, and Miller (1994), who correlated counts of papillae and taste buds with taste sensitivity.

Stimulation of Receptors

Saliva is an important component of taste function. It acts as a solvent and enables contact between the taste stimulus and the plasma membranes of the gustatory hairs, where a generator potential initiates a nerve impulse. Moistening of the mucus membrane in the mouth by saliva is increased when food is in the mouth.

Chewing stimulates secretion of saliva via receptors in the brain stem known as the superior and inferior salivating nuclei (Tortora & Anagnostakos, 1984). The stimuli of thought, sight, and smell may lead to anticipation of taste sensation before the food is placed in the mouth, resulting in saliva secretion. These stimuli are based on learned behavior, memory, and psychological response and form the basis for the expression, “It makes my mouth water.”

Primary Tastes

It is generally accepted in sensory science that there are four primary tastes that stimulate taste buds at specific areas of the tongue. Each primary taste is designated as such by the responses of taste buds to different chemical stimulants. Studies on single taste buds have demonstrated that most taste buds can be stimulated by more than one primary taste stimulus (Collings, 1974). As a general rule, however, the specificity theory works well for demonstrating the taste sensation of each of the four primary tastes: sweet, salty, sour, and bitter. Sweet is the sensation recognised predominantly at the tip of the tongue, salty and sour sensations at the sides, and bitter at the back. The standards used to demonstrate the primary tastes are based on solutions of sucrose (sweet), sodium chloride (salty), citric acid (sour), and quinine sulphate or caffeine (bitter).

Some substances normally associated with one particular taste sensation may demonstrate other taste sensations over a range of concentrations. Saccharin, which has considerable use as an intense sweetener, can taste bitter as well as sweet. Work by Helgren, Lynch, and Kirchmeyer (1955) demonstrated that some individuals recognize a bitter taste in saccharin at certain concentrations. This bitterness was originally thought to be due to different preparation procedures but was shown in the study to be inherent in the particular structure of the saccharin molecule to which some individuals demonstrated sensitivity.

Another example of differences in taste sensitivity between individuals is the phenomenon of bitter taste blindness. This was originally studied using phenylthiourea (phenylthiocarbamide). Fox (1932) and Blakeslee (1932) discovered that 20% of the population were unable to detect any bitterness in solutions of the compound. More recent studies into taste blindness have been carried out using the compound 6-n-propothiouracil, which correlates with the phenylthiourea response but is less toxic (Lawless, 1980).

When examining responses to primary tastes, it has been shown that some individuals confuse bitter with sour. This occurs not because of a lack of ability to differentiate but because the two primary tastes are frequently present together in many products, such as lemons and grapefruit. This confusion can easily be rectified by demonstration using standard solutions.

Threshold Levels

Absolute or detection threshold is the lowest perceivable energy level of a physical stimulus, or the lowest perceivable concentration in the case of a chemical stimulus (Lawless & Heymann, 1998). Recognition thresholds are the minimum levels of concentration at which the characteristic taste of stimulant is evident. As a general rule, the concentration of the recognition threshold is slightly higher than that of the detection threshold.

Absolute thresholds vary between individuals and even with a single individual. Sensitivity is affected by emotional and environmental factors as well as by the substance under investigation. Difference thresholds relate to the amount by which a stimulus must change before it becomes a just noticeable difference (JND). Early work on this by Weber and Fischer forms the basis for much of today's sensory methodology (Amerine, Pangborn, & Roessler, 1965).

Measurement of threshold levels has been used extensively in studies of the psychophysics of taste. This concerns the functional relationship between stimulus and response. That is, the physical stimuli are measured and related to psychological sensation (Coon, 1986).

Adaptation of Taste

Continuous stimulation of the sense of taste, as with the other senses, results in adaptation. This occurs very quickly after contact with the taste stimulant but is slower after 2 to 3 seconds. Complete adaptation to taste can occur in 1 to 5 minutes and involves a psychological adaptation in the central nervous system (Tortora & Anagnostakos, 1984). When food is being tasted, adaptation involves the senses of both taste and smell.

Taste and Flavor

Flavor is the total sensation realized when a food or beverage is placed in the mouth. The senses of smell and taste involve chemoreceptors, and it is the combination of these with other receptors such as the mechanoreceptors of touch and electromagnetic receptors of sight that leads to the overall perception of flavor. When food or drink is consumed, the primary tastes are recognized on the tongue along with textural and other associated sensations in the mouth and on the palate. Identity is conferred as a result of the movement of volatile components of the food from the back of the mouth into the olfactory area, where the smell mechanism operates. Often when a loss of the sense of taste is indicated, it is really a loss of the sense of smell (Murphy & Cain, 1980). This situation arises with people suffering from the common cold or from an allergy and who complain that they cannot taste. In fact, their taste sensations may not be impaired; the olfactory mechanisms are affected because volatile components from foods are prevented from entering the olfactory system by mucus.

Taste Aversion

Taste acceptance varies considerably between individuals and also with single individuals. Cabanac and Duclaux (1970) demonstrated that hunger influences the degree of acceptability and pleasantness of the sweet taste. Acceptance and preference in relation to food quality depends on a combination of physiological and psychological response. Taste aversion is a type of classical conditioning that occurs when illness follows consumption of a partic-

ular food; a negative association is developed with that food, which is subsequently avoided (Logue, 1986). Taste aversion can also occur as a result of drug treatment, especially in cancer patients (Bernstein, 1978; Bernstein & Webster, 1980).

Umami

The four taste qualities sweet, sour, salty, and bitter are adequate for most investigations involving sensory evaluation. Umami is the description for the mouthfilling sensation of monosodium glutamate (MSG), 5^1 inosine monophosphate (IMP), and 5^1 guanine monophosphate (GMP; Kawamura & Kare, 1987). Often described as flavor enhancers, these substances are the subject of ongoing discussions on whether umami can be considered as a separate taste category.

TELEOLOGICAL PSYCHOLOGY

The word *teleology* devolves from the Greek *telos,* which means an end in the sense of an intended goal or target for the sake of which behavior is carried out. Something that is done intentionally can be said to begin in choice, or to serve a purpose. The adjective *teleological* (or *telic*) in the phrase teleological psychology thus tells us that here is a psychology in which organisms—especially human organisms—behave as they do after they have put down or framed some kind of predicating assumption. Meaning is vital here. As any dictionary will reveal, "to mean" is literally "to intend." This style of explanation places a good deal of responsibility on the behaving individual. In contrast, a nonteleological psychology would deny that people have actual control over their intentions and purposes, for they are under a continuous shaping by their heredity and environment. This style of explanation is termed a mechanical psychology. For centuries, there has been a dispute between the teleologists and the mechanists in disciplines such as religion, philosophy, and science. To date, psychology has been predominantly in favor of mechanistic accounts—at least in academic centers. Nevertheless, the ancient debate over the nature of behavior continues.

To understand more fully the disagreement between the two types of psychology we must first grasp what it means to say that anything existing has been *caused* in some fashion. Aristotle advanced the ruling theory of causation, in which he named four kinds of causes as being responsible for a thing's existence or an event's occurrence. First is the material cause, or substance (e.g., wood, mud, flesh, bone matter) that "makes things up." Next is the efficient cause, which provides the thrust to move things along or assemble them in some way (energy, gravity, electricity, etc.). A third responsibility is the formal cause or pattern in events as well as the various shapes that things assume in becoming recognizable (a tornado, mathematical equation, plan, etc.). Fourth, we have the final cause, by which is meant the reason, purpose, or intention for the sake of which things exist or come about (goals, retributions, plans, etc.).

There are at least three kinds of teleological theories found in the history of philosophy: human, natural, and deity. We see a human teleology in Socrates' (470–400 BC) dis-

cussion of businessmen risking dangerous sea voyages for the sake of a possible profit (an end that motivates things). There is also a natural teleology, as when Aristotle (384–322 BC) suggests that leaves on the branches of trees exist for the sake of providing shade for the fruit that grows on them, concluding thereby that nature is always involved in some form of purpose. We also have various forms of deity teleology, which claim that the natural order unfolds for the sake of a divine plan reflecting the deity's intention. This latter use of final causation was to bring telic description into decline in science.

Most philosophers in the empirical tradition retained their belief in a deity, but they fashioned a rigorous method of practicing science that did not rely on such a deity teleology to make its descriptive case or to establish its validity. The aim of all so-called proper natural scientists was to reduce observed identities and actions to underlying mechanical processes. In effect, *reductionism* means to reformulate formal and final cause explanation into material and efficient cause explanation.

Teleological explanation drew precedents from continental philosophy. The tie binding all these views is an appreciation of the role that human conceptualization (mind) plays in the understanding and creation of experience (reality). Reductionism is rejected in favor of a form of human teleology in which the person is viewed as framing the reason, creative purpose, or willful intention for the sake of which behavior is carried out.

It could be argued that psychology as a unique scientific discipline began with G. T. Fechner's desire to prove that human beings are in fact teleological organisms. His distinctive psychophysical methods (average error, constant stimuli, limits) and famous (Weber-Fechner) law were the combined fruits of Fechner's efforts to show that consciousness (telic mind) was the inner patterned unity of a corporeal system (nontelic matter). However, he brought a deity as well as a human teleology into his telic explanations, which turned away colleagues and students alike.

Hermann von Helmholtz more than anyone else influenced the early course of psychological explanation, sending it in the direction of reductionism. He argued that the constancy principle (conservation-of-energy principle) applied with equal validity to the explanation of human behavior as to the explanation of inanimate, physical events. Psychologists must reduce behavioral explanation to basic forces, according to Helmholtz. Concepts of mass energy, force, and thence motion were familiar to Newtonian physics, which construed them in terms of *only* material and efficient causation. Such scientific explanations turned nature into a complex mechanism in which no deity's plan or human's intention played a role whatsoever. In a fascinating historical parallel, the youthful Sigmund Freud was to be influenced by Brucke to frame the libido theory of psychoanalysis, which reduced thoughts to underlying forces in the constancy-principle sense.

Advocates of an openly teleological explanation of behavior have been prevalent in psychology. Both Alfred Adler and Carl G. Jung endorsed teleological explanations of the human being. In the more academic circles, William James' fiat of will and William McDougall's purposive psychology were early efforts to add to the Helmholtzian reductionism a formal-final causal explanation that ever eluded it. Notable efforts to provide a telic side to behavioral description can be seen in Gordon Allport's functional autonomy and in Gardner Murphy's concept of canalization. A classic confrontation occurred when Carl R. Rogers (teleologist) debated B. F. Skinner (mechanist) over whether people had freedom and control in their personal behavior. No final decision was reached, of course.

A view being advanced by a growing number of psychologists today is that there may be room for teleological explanations in their field. Difficulties with the mechanistic conception of reinforcement in conditioning adult humans have led these psychologists to question the assumption that behavior is manipulated without a person's conscious awareness of what is taking place and a resultant intention to carry out the implications of such knowledge. Relying on formal and final causation to account clearly for such behavior may be introduced in the not too distant future.

TERRITORIALITY I

Territoriality refers to behavior associated with the acquisition, maintenance, and defense of a territory. In animals, territories are geographical areas that surround the home. These areas are protected from other members of the same species, and normally conspecifics are not even allowed entry. In humans, the concept of territoriality is similar, but it often takes different forms.

In animals, territoriality is usually thought of as instinctive and adaptive behavior. Because each group is separated from the others, the density of a population can be maintained at a level that facilitates food gathering, reproduction, and the control of aggression. These spaces can change in size.

Territoriality in humans takes more flexible forms. It is unclear whether this behavior in humans has instinctual or learned origins, but it is certain that people's use of territories is different from that of animals. First, there are several different kinds of human territories. People typically have one or two *primary territories,* such as the home or office, which are places in which a great deal of time is spent and that are owned and personalized on a more or less per-

manent basis. People also have *secondary territories,* defined as places where they spend less time and in which ownership is transient. People control secondary territories only when they are in them. Public territories are places that people use but that are not owned by an individual or a small group. Parks, beaches, and other such areas are public because they are owned by an extremely large group.

Humans are also more flexible than animals in their defense of territory. Social and cultural mechanisms that fulfill many of the survival needs provided by territoriality among animals make defense of territory less often necessary among people.

The ways in which animals and humans denote territorial control also differ. Many animals rely on scent to notify others that they own a space, such as by urinating along its boundaries to provide clear cues. Humans typically use visual markers. Studies have indicated that people paint and decorate territories to denote ownership.

Aggressive defense of territory does occur among humans, although less often than among animals. This defense often takes milder forms than fighting. In the case of defense of well-established territories, physical aggression is less likely to occur.

Andrew S. Baum
University of Pittsburgh Cancer Institute

TERRITORIALITY II

There is disagreement concerning the best way to define territoriality. Classically, a territory is any defended area.

Animals of many species occupy specific portions of their habitats from which they exclude other members of the species. A male stickleback fish in breeding condition will defend an area around a nest against intruding males. This is the essence of territoriality. What is remarkable is that an animal that might lose a contest in a neutral area or in the territory of another individual typically will win while in its own territory.

Perhaps the most important fact concerning territories is the diverse nature of different patterns grouped together under this one term. Wilson lists five types. Type A territories are large, defended areas within which animals can mate, court, and gather most of their food. Various species of fishes, lizards, and birds occupy such all-purpose territories. Type B territories also are relatively large and are used for breeding, but the residents go elsewhere to feed. Nightjays and reed warblers occupy such territories. Type C territories are small defended areas around a nest, as found in many colonial birds. There is room for little more than breeding. Type D territories are pairing or mating territories; animals go to these territories to mate but, in contrast to the first three types, raise their young elsewhere. Birds such as the sage grouse and ungulates such as the Uganda kob form such leks. Type E territories are the roosting positions or shelters used by many species of bats, starlings, and domestic pigeons.

Thus territories vary along several dimensions. They may or may not be used for feeding, mating, or rearing of the young, depending on the species. The number of residents varies from a single male, a mated male–female pair, or a whole group of animals that defend the territory. Most territories relate to a fixed location. An interesting borderline case can be found with bitterlings, a small species of fish that lays eggs in the mantle cavities of certain species of mussels and that defends the area around the mussels, even if they move. It is important when trying to generalize from territory in animals to similar phenomena in humans that one remember the diversity of animal territoriality.

Territorial defense need not always entail overt fighting; song or odors can serve to mark an area as occupied. In a typical experiment on the function of bird song, some males are removed from their territories and replaced with loudspeakers that do or do not continue to emit the songs. Intrusion by conspecifics is delayed when songs are played. In other experiments, devocalized males have difficulty in keeping out intruders. It seems as though males must sing to keep their space.

The concept of territory often has been applied to humans in a variety of contexts. Members of a nation may defend a border, members of a gang may defend their turf, and suburban homeowners may defend their property. Indeed, Sebba and Churchman looked within the homesite to view the dwelling unit as composed of segments of space appropriate for use by different individuals or clusters of individuals. In another experiment, androstenol was shown to be a human odor that functioned to space males. By treating half of the stalls in a public restroom with the chemical, the experimenters found males to avoid marked territories. Models of economic defensibility in relation to resources have been applied to human populations by anthropologists.

Donald A. Dewsbury

TERTIARY PREVENTION

The concept of tertiary prevention arises from the public health preventive services model (Commission on Chronic Illness, 1957; Last, 1992). In this model, preventive services are categorized into primary, secondary, or tertiary interventions. The goal of primary prevention is to decrease the prevalence of disease via reduction in its rate of occurrence.

Primary prevention is therefore directed at eliminating etiologic factors, thereby reducing the incidence of the disease or eradicating it entirely (Greenfield & Shore, 1995). A classic example of primary prevention is the use of immunization against measles and rubella to eliminate neonatal neurological impairment caused by these diseases. Secondary prevention works to reduce prevalence (a function of both duration and rate of occurrence of the illness) by decreasing the illness's duration through early intervention and effective treatment. Tertiary prevention refers to interventions that aim to reduce the severity, discomfort, or disability associated with a disorder through rehabilitation or through the reduction of the acute and chronic complications of the disorder (Fletcher, Fletcher, & Wagner, 1988; Mrazek & Haggerty, 1994).

Certain interventions may be considered to be either secondary or tertiary prevention. For example, the use of psychotropic medications and psychotherapies may serve at different times as secondary or tertiary preventive measures. Early intervention and use of these as effective treatments can decrease the duration of the illness and may represent secondary prevention. However, in individuals with a chronic relapsing illness, the use of psychotherapy and psychotropic medications to prevent relapse to a symptomatic stage of the illness would constitute tertiary prevention. For example, maintenance antidepressant medication to prevent relapse to a symptomatic stage of mood disorder can be viewed as tertiary prevention. Another example would be the use of group psychotherapy to prevent relapse in currently abstinent individuals with substance use disorders. Other interventions that diminish social impairment or disability among those with chronic conditions also represent tertiary prevention—for example, vocational rehabilitation or social skills training for those with chronic psychotic disorders. Overall, most tertiary preventive interventions for psychiatric disorders fall into the category of maintenance treatments for chronic conditions. Such maintenance interventions include (1) interventions that are aimed at increasing compliance with long-term treatment and whose goal is to reduce relapse and recurrence and (2) aftercare treatments, such as rehabilitation, whose goal is to improve social and occupational function (Mrazek & Haggerty, 1994).

Examples of Tertiary Prevention

Most examples of tertiary prevention within mental health are found in the maintenance, treatment, and rehabilitation of individuals with chronic mental disorders. Schizophrenia is a chronic psychotic disorder with onset usually in late adolescence and an overall prevalence in the United States of approximately 1%. The combination of relatively high prevalence and early onset imposes a large burden of personal suffering and need for treatment and rehabilitative services due to the morbidity and chronic disability the disorder engenders. Tertiary preventive interventions are, therefore, quite important in this population in the form of rehabilitation and prevention of relapse (Preventing schizophrenic relapse, 1995). Medication nonadherence may be responsible for 40% of all exacerbations of schizophrenia that result in hospitalization. In addition, the illness generally interferes with a number of areas of functioning.

A number of tertiary preventive interventions have been designed to improve functioning, increase medication adherence, and reduce relapse, and thereby decrease overall disability due to the illness. Comprehensive psychosocial treatments such as those involving Assertive Continuous Care (Stein, 1990) and behavioral rehabilitation (Anthony & Liberman, 1986; Liberman, Falloon, & Wallace, 1984) can improve patients' medication adherence and help with a number of psychosocial aspects of life, including vocational and recreational activities. For example, behavioral rehabilitation uses a multidisciplinary team to provide services that can help increase adherence to medication and provide support and direction in other areas of the patients' lives, including work, family, and social interactions (Kopelowicz & Liberman, 1995).

Depressive disorders are among the most common psychiatric disorders. For example, the prevalence of major depressive disorder at any one time is estimated to be 2% to 4% in the community, 5% to 10% among primary care outpatients, and 10% to 14% among medical inpatients (Katon & Schulberg, 1992). Depressive illness is generally chronic and relapsing and can have significant social and economic consequences for the affected individual (Montgomery, Green, Baldwin, & Montgomery, 1989). Tertiary prevention of depressive disorders, therefore, usually focuses on decreasing the likelihood of relapse and recurrence. At least 50% of recurrent episodes of depression are preventable by adequate prophylaxis with antidepressant medication (Montgomery et al., 1989). For major depression, antidepressant treatment for a minimum period of 6 to 9 months following the resolution of symptoms is indicated to decrease the risk of recurrence. In addition, a common tertiary preventive intervention for bipolar disorder is maintenance medication with a mood stabilizer with or without an antidepressant to minimize the risk of another manic or depressive episode (Goodwin & Jamison, 1990).

Tertiary prevention of substance use disorders involves relapse prevention and rehabilitation. Considerable evidence suggests that patient involvement in ongoing treatment is helpful in maintaining abstinence, limiting the total duration of relapses, and improving overall long-term outcome (Greenfield & Shore, 1995; Higgins et al., 1994; McLellan, Luborsky, Woody, O'Brien, & Druley, 1983; O'Malley, Jaffe, & Chang, 1992). Programs that help individuals maintain abstinence from substances or limit the duration of relapse are effective tertiary preventions; they include aftercare participation such as training in relapse prevention or coping skills, behavioral treatment, involve-

ment in Alcoholics Anonymous, and methadone maintenance (Galanter & Kleber, 1999).

TEST STANDARDIZATION

Test standardization is the establishment of uniform procedures for test administration and scoring. If psychological measurement is defined as the use of rules to assign numbers to relative quantities of psychological constructs associated with persons, then test standardization is the determination and explication of those rules. Without standardization, measurement is only an informal process that varies from examiner to examiner. Historical impetus for the concern with control on the part of examiners arose from nineteenth-century experimental psychologists from Leipzig, where work demonstrated that minor variations in giving instructions and making observations resulted in differences (Anastasi & Urbina, 1997). The first standardized tests appeared in the early part of the twentieth century, when E. L. Thorndike and others extended the principles learned in a laboratory to psychological measurement. DuBois (1970) elaborated the history of standardized testing.

The *Standards for Educational and Psychological Testing* (American Educational Research Association et al., 1999) provides an outline of procedures that test publishers and users should follow to ensure proper implementation of standardization procedures. Control of test administration procedures is largely accomplished by instructions specified in test manuals. For example, test authors must develop test manuals that clearly describe (1) test administration directions under which norming, reliability, and validity data were gathered and (2) scoring directions to minimize scoring errors. Regarding directions for test administrators, such matters as time limits, procedures for marking answer sheets and scoring tests, and instructions for guessing must be provided in the test manual. Those conditions under which changes to test administration procedures may be made and how questions from test takers should be answered should be specified. Clemens (1971) provided detailed consideration of test administration (mostly for tests administered in group settings). Regarding procedures for scoring test responses, the *Standards for Educational and Psychological Testing* (1999) specify that detailed instructions for scoring both subjective and objective tests should be furnished in the test manual, and, in the case of subjectively graded tests, the extent of agreement between scorers should be enumerated, differentiating the extent of interscorer reliability by levels of scorer training, if possible. Manuals should detail qualifications needed to administer and score the test in question. Test users are expected to follow carefully the standardized procedures as described in the manual when administering a test and, given these procedures, to enable all test takers to perform their best. One should keep favorable conditions for testing consistent with standardization procedures. Test users are charged with checking all details of test scoring meticulously for accuracy.

Another aspect of test standardization is the development of test norms. To establish norms, a test constructor administers the test under standardized conditions to a large, representative sample. Representative means that the sample resembles the persons for whom the test is intended. The data from this experimental testing allow the test constructor to identify the normative or typical behavior (e.g., the 50th percentile) and other percentiles. These values, in conjunction with reliability and validity information, permit professional test users to interpret test scores properly.

Three potential advantages of standardized psychological tests are evident. First, standardized tests are frequently of higher quality than locally constructed tests. Because these tests may be employed by a large number of client-users, much more expense and professional time can be spent at all stages of the test construction (e.g., preparing test outlines, editing items, item analysis, test revision, etc.). Second, using standardized examinations may free psychologists and other professionals from spending time on test construction and other evaluative activities and permit them to employ time on other more important matters—therapy, instruction, and score interpretation. Last, the use of standardized measures facilitates communication among professionals. Scores on tests administered under proper conditions communicate information about individuals, groups, and scientific findings effectively to others. One important disadvantage of standardized measures is that due to their availability, standardized tests may be used inappropriately. For example, a standardized selection test for industry might be used in a situation in which it has neither been intended nor validated. Similarly, a local school program with unique goals could not be effectively evaluated with a nationally standardized test with its broad-based orientation.

The term *standardized tests* is sometimes applied to those tests that are simply extensively (e.g., nationally) normed. However, norms are usually useful only if they relate to test scores achieved under uniform conditions. In fact, before norming a test can begin, detailed conditions of standardization must be finalized and described for examiners. Tests administered under conditions differing from those for which the test is intended will yield scores that are difficult to interpret.

One special case of test score interpretation where tests often must be administered under nonstandardized conditions is for individuals with disabilities. The Americans with Disabilities Act (1990) requires that tests be administered with appropriate accommodations. That such groups of test takers are small makes validation and interpretation more difficult (Geisinger, 1994; Sandoval, Frisby, Geisinger, Schennemann, & Grenier, 1998), but early validation efforts with nationally standardized college admissions measures seem promising (Willingham et al., 1988).

TESTING METHODS

The development of tests in psychology is undoubtedly one of the greatest contributions of psychology as a discipline. Psychology has evolved as a useful discipline in a large variety of institutions in our society (e.g., clinical and counseling settings, industry, medicine, and the schools) primarily because of its model of diagnosis and treatment (Anastasi, 1979), in which treatments are applied largely on the basis of assessments made about the current functioning of an individual, group, or organization. Assessments of many different kinds can be made, and it is probably safe to report that if one can imagine every possible human characteristic, behavior, thought pattern, or tendency, some psychologist has attempted to measure it. The many kinds of psychological measurement can be typified along a variety of facets, some of which are best identified as dichotomies and others as continuous.

One of the primary issues in differentiating psychological measures relates to the content of the domain that is being measured. Specifically, most psychological constructs that are measured can be identified as either cognitive or noncognitive measures. Cognitive measures include those that assess normal abilities (e.g., intelligence), special abilities (e.g., artistic or quantitative aptitude), and achieve-

ment (which tends to be information and concepts learned in instructional programs). Noncognitive measures generally assess personality, interests, attitudes, beliefs, and so on. One operational difference between the two domains is that questions on cognitive measures tend to be answered correctly or incorrectly or in some cases to vary in their degree of correctness. Noncognitive measures, on the other hand, measure the strength of one's tendencies, sometimes in a bipolar manner. Thus, scales may have two endpoints, such as masculinity-femininity or introversion-extraversion. Responses to questions or ratings that place a respondent along a continuum concerning one of these dimensions are not correct or incorrect; they simply represent differences. This fundamental distinction among cognitive and noncognitive measures in psychology is quite important.

Within cognitive measures, one of the most important and common distinctions is that of ability and achievement. The distinction between abilities and achievement is one of degree, although these characteristics are often mistaken to be qualitatively different, a difference where some occasionally falsely perceive abilities as genetically determined and achievement as rather environmentally influenced. Anastasi and Urbina (1997) defined achievement tests as "designed to measure the effects of a specific program of instruction or training" (p. 475). Achievement tests measure the effects of relatively uniform experiences, especially of instructional events. Ability tests assess behavior that is manifested based on the cumulative influence of the many experiences of all aspects of life. Both ability and achievement reflect learning from one's environment; however, ability tests measure the effects of learning under relatively uncontrolled and often seemingly random life conditions, whereas achievement tests measure the effects of learning that occurred under more known and controlled conditions (Anastasi & Urbina, 1997).

Another major distinction among methods of psychological measurement concerns the nature of the responses by the test taker—specifically, whether the test taker responds with a constructed response or selects a response from among a number of possibilities. These distinctions can relate to the measurement of almost any psychological characteristic, whether cognitive or noncognitive, and they are most often written. On typical classroom tests developed by teachers, for example, a fill-in-the-blanks-type question is a constructed response question, and a multiple-choice question is a selected response question. Selected response questions are generally much easier to score quickly and are hence known as objective-type questions. Essay tests and other types of educational products (e.g., realistic samples of schoolwork performed by students or work samples provided by employees) are much more difficult to score and generally involve expert judgment (Coffman, 1971; Wiggins, 1973). Within the area of personality, measurement can also differ along this dimension. Objective-type measures use true-false or similar types of questions and typically match responses to representative patterns provided by previously identified groups of people. Projective techniques are a common kind of personality measure in which the examined individual provides an interpretation of relatively unstructured stimuli, such as ink blots or ambiguous pictures. The examiner provides a structure to the response in scoring it. These scoring methods, whether for essay questions or projective techniques, must be carefully and explicitly developed in advance to ensure both reliable and valid responses and interpretations of such responses (Wiggins, 1973). Professional test developers attempt to align the types of tests and test components or items (such as multiple-choice, fill-in, essay, short written answer, oral responses) to the nature of the characteristics or knowledge being assessed (Adkins, 1974; Hakel, 1998; Millman & Greene, 1991). Oral responses are common in individually administered tests.

Tests may be administered a number of different ways. Many tests (e.g., many intelligence tests and projective personality measures) are given by a professional examiner to individuals one at a time. Group tests are administered to a number of test takers at one time and often tend to be objectively scorable. Increasingly, many measures are administered via computer. Individual and computer-based tests can adapt to the responses of the test taker. For example, in many computer-adaptive tests (CATs), answering questions correctly sends one to more difficult questions, whereas incorrect responses lead to easier questions in the attempt to assess the test taker most accurately using appropriate questions. A testing professional who administers a test individually can ask probes or appropriate questions and can make certain prescribed test adaptations in accordance with the procedures for test administration as described in the test manual.

Tests can be purchased or built locally by professionals. The former tests are typically called standardized (see "Test Standardization") and are typically sold by test publishers, and the scores or results can be interpreted in terms of norms (statistical distributions of the population of individuals who have taken the test). Norms are typically useful only if they relate to test scores achieved under uniform conditions. Most locally constructed tests do not have such norms or interpretative information, but they may be specifically adapted to the local use in question.

All psychological measures are evaluated using similar criteria, such as test validity. These criteria are explained briefly in "Psychometrics" entry and in a more elaborate fashion in Anastasi and Urbina (1997) or the *Standards for Educational and Psychological Testing* (American Educational Research Association et al., 1999).

THEORETICAL CONSTRUCTS

It is relatively easy to name directly observable behaviors like eating and running. What accounts for these behaviors is a much more difficult task. When the relevant antecedent conditions are known, such as the presentation of a noxious stimulus (for running) or the presentation of food after it has been withheld (for eating), researchers can begin to understand such behaviors. But there is more to the problem than simply identifying antecedent conditions. Attributing overt behaviors to presumed covert intraorganismic functions, such as fear and hunger, requires the naming of those functions. Such naming is essentially the problem of theoretical constructs.

Hypothetical Constructs and Intervening Variables

Theoretical constructs within psychology are thus hypothesized internal processes presumed to underlie specified overt behaviors. An influential distinction between two types of such constructs was made by MacCorquodale and Meehl. Hypothetical constructs are defined as complex internal processes with meanings that are not entirely confined to the relationship between the stimulating conditions and the ensuing behaviors (i.e., they contain surplus meaning). The basic problem with the hypothetical constructs as thus defined is that the presence of such additional, unspecified meaning allows an indeterminate amount of ambiguity to cloud the fundamental definition of the construct and so reduce its theoretical usefulness.

Intervening variables are more restricted concepts. Their meanings are strictly circumscribed by the specified stimulus-response relationships (i.e., the antecedent environmental conditions and the consequent behaviors). The intervening variable is whatever occurs within the organism (presumably within the brain) that accounts for the observed stimulus-response relationship.

Such narrow definitions are not easy for psychologists to live with. Intervening variables as thus defined have been criticized as being sterile. This criticism is rebutted by pointing out that it is not the intervening variable itself that should be so accused but the theoretical use to which it is put. That rebuttal notwithstanding, intervening variables were never popular in psychological theory construction and seem to have become less popular in recent years. Nevertheless, at least some approximation to a fully operational definition, such as is provided by the intervening-variable type of construct, holds promise for more effective theorizing in psychology. Some examples may help to support this opinion.

Examples of Intervening Variables

Here, two uses of intervening variables are considered that illustrate their potential value, especially as tools in the development of theory. Mowrer and Viek kept all laboratory rats in their experiment hungry. They allowed rats in the experimental group to turn off noxious electric shock by jumping off the floor. The shock was given 10 seconds after the rats started to eat food offered on a stick pushed up through the floor bars. Matched controls in contiguous cages had a shock of exactly the same intensity and duration, but these rats were unable to turn it off. The rats in the experimental group ate more of the food and started to eat faster than the control rats. This difference could not be attributed to any physical difference in the shock. Mowrer and Viek explained the behavioral difference by attributing a sense of helplessness to the control rats. The subsequent development of the learned helplessness problem, in which first animal and later human subjects were used, illustrates the way in which more extensive experimental and theoretical work can have both broader and deeper ramifications than an initial experimental demonstration of an intervening variable.

In a second early experiment, modeled on the Mowrer and Viek experimental design, Marx and Van Spanckeren used seizure-sensitive laboratory rats (subjects that had been found to be susceptible to seizures—then called audiogenic—when stimulated by high-frequency, high-intensity sound in a physically restricted environment such as a cage). Vertical poles were placed in the centers of two contiguous cages. An experimental and a control rat, matched for susceptibility to seizure on the basis of prior tests, were

then placed in the contiguous cages and the noxious sound stimulation presented. The experimental rat was able to turn off the sound by tilting the pole; the control rat could not do so. Because the sound stimulation came from a centrally located speaker, placed between the cages, any behavioral differences could not be attributed to strictly physical factors but could be attributed to the difference in treatment (i.e., to the more active role of the experimental rat in the management of the noxious stimulus). The results were that the control animals showed both quicker and more frequent seizures. Marx and Van Spanckeren attributed this difference to a presumed sense of control in the experimental rats, thus offering a positive internal function as an intervening variable to account for their greater resistance to seizure.

Contributions of Tolman and Hull

The use of intervening variables in psychological theory was first suggested by E. C. Tolman. Tolman later stated that he had come to favor the more comprehensive, less restricted hypothetical construct. Looking back on his earlier theoretical work, he commented,

> My intervening variables are generally speaking mere temporarily believed-in, inductive, more or less qualitative generalizations which categorize and sum up for me various empirically found relationships. . . . And they are not primarily neurophysiological . . . but are derived rather from intuition, common experience, a little sophomoric neurology, and my own phenomenology.

Clark Hull, in developing a grandly conceived hypothetico-deductive behavior theory, attempted to use intervening variables (e.g., habit strength, reaction potential, and inhibition) in a much more systematic and formalized manner. He used them as both theoretical tools—stimulants to and directors of empirical research—and theoretical concepts embedded in the propositions of his formal theory. There was much criticism of these intervening variables, which were regarded as too specific for the theory (e.g., specifying the weight in grams of the food rewards in some of the research with rats).

An Operational Continuum

It is helpful to think of the hypothetical concept and the intervening variable as belonging on opposite ends of an operational continuum rather than as discrete, absolutely different types of constructs. Progressive improvement in the operational clarity of theoretical constructs can then be regarded as a more reasonable objective in psychological theory construction than any quick-fix of constructs with ambiguous or unspecified meanings.

The intervening variable seems to be more appropriate when used as a tool in theory construction than when used as an element in a fully formalized theory. Scientists are well aware that the phenomena they investigate are complex and not readily reducible to such interpretations. If the more straightforward and simplified concepts, such as intervening variables as here defined, are to be of maximum value, they must be gradually introduced and carefully refined in preliminary types of theory construction or theorizing. Attempting premature placement in highly formalized theory, as Hull did, is to invite rejection.

THEORIES OF FAMILY DEVELOPMENT

General Description and Early Formulations

Family development theory focuses on changes over time in family structure, roles of family members, developmental tasks, stressors and crises, and adaptive and maladaptive coping mechanisms. Historically, theorists conceptualized the family development as consisting of predictable stages and normative transitions through which most families evolve across the life cycle. E. M. Duvall's early work in the late 1950s, for example, defined the family life cycle as consisting of eight developmental stages: (1) married couple without children; (2) childbearing families (oldest child from birth to 30 months); (3) families with preschool children (oldest child from 2.5 to 6 years); (4) families with school-age children (oldest from 6 to 13 years); (5) families with adolescents (oldest from 13 to 20 years); (6) families that are launching children from the home (from first child to last child to leave home); (7) middle years including empty-nest syndrome to retirement; (8) and aging families extending from retirement to the death of both spouses. Duvall's model focused on the intact nuclear family (two biological parents living with their children)—the most common family structure at the time—and was based on the assumption that most families evolve through this predictable sequence of stages in accordance with a similar timetable.

Reformulations of Stage Theories

Coinciding with the dramatic rise in marital transitions (e.g., divorce, remarriage, and redivorce) in subsequent decades, R. Hill and other family theorists formulated more complex stage theories (i.e., greater variability in the number, types, and timing of stages with concomitant alterations in developmental tasks) taking into account the prevalence and diversity of single-parent families and stepfamilies. Considering a divorce rate of nearly 50% extend-

ing over three decades and the fact that most divorced people remarry (many of whom have children from prior marriages), the burgeoning diversity of family structures required a reformulation of Duvall's original theory of the family life cycle. Stage theories persisted but were now defined in terms of marital stability or instability, whether one or both remarried partners had children from prior marriages (i.e., simple vs. complex stepfamilies), custody arrangements (e.g., stepfather vs. stepmother families), the presence or absence of children from the remarriage (i.e., his, hers, and ours), and the ages and life-cycle stages of individual family members. In addition, family development theorists, buttressed by a plethora of empirical research comparing these permutations and combinations of family structures, became aware that the developmental tasks and concomitant functional and dysfunctional coping mechanisms varied widely across these diverse and changing family forms. Adaptive mechanisms for coping with life-cycle changes often differed from what worked in traditional nuclear families. For example, biological parents disciplining and showing affection to children may be adaptive, but the same parenting practices in newly formed stepfamilies often backfired and was maladaptive.

Challenges to Stage Theories of Family Development

The increasing diversity of family structures beyond those formed as a result of marital transitions (e.g., couples who live together but never marry, never-married parents, families of different cultures and racial groups, biracial couples, gay and lesbian couples, etc.) has led family development scholars in recent years to question the universality assumptions (i.e., families evolve through similar life transitions) of prior theories as well as the capacity of stage theories to capture the inordinate variations in life cycles of all families. Moreover, transitions that still occur in most families (e.g., birth of a first child) may occur simultaneously or in close temporal proximity to other changes and stressors (e.g., divorce, death of parent), which, within the context of different cultural groups and family structures, make the prediction of the types and timing of life changes exceedingly difficult. Additional problems with stage theories include their overly parsimonious focus on single generations in defining stages (e.g., aging families are comprised of members at other generational levels; the launching stage focuses on parents and deemphasizes adolescents and young adults who are leaving home) and their inadequate attention to family processes and the interdependencies of individual growth trajectories and those of families as a collective unit.

Beyond Stage Theories: The Search for Unifying Frameworks

Family development theorists have begun to identify unifying frameworks that transcend stages, address both the commonalities and diversities of family life, adopt a multigenerational perspective, and consider the intersections of individual and family change processes. For example, T. Laszloffy recently articulated a systemic family development (SFD) model, which integrates family crisis theory and family systems theory in conceptualizing families' and individuals' responses to stressful life events and transitions. According to SFD, common processes that all families experience are external and internal stressors that challenge family members to change their roles and interactional patterns in order to cope effectively. In accordance with H. McCubbin's family crisis theory, families cope adaptively (i.e., make the necessary changes) or maladaptively (i.e., get stuck and experience a crisis) depending on an interaction of family members' individual and collective coping resources as well as their interpretations of the stressful events. A pileup of stressors (i.e., multiple stressors occurring within a short period of time) presents a greater challenge to a family's capacity to adapt. Families differ, however, in the number, types, and timing of stressors and life transitions; in their coping resources and interpretations of stressful events; and in whether specific stressors or combinations of stressors lead to crises or successful reorganizations in structure and process. The SFD model also directs attention to a multigenerational model in which different generations within the same family may experience developmental stressors simultaneously (e.g., the first generation begins school, the second generation moves across the country, and the third generation experiences death of marital partner); and, consistent with family systems theory, the effects of stressors on individuals across generations are presumed to be interdependent (e.g., how the second generation copes affects how the first and third generations cope) and varied in their effects on individual family members and the family as a whole.

Consistent with D. Cicchetti's structural-organizational perspective on individual development, a new generation of family development theorists is considering whether families' successful mastery of prior developmental challenges enhances competencies and expectations for success and hence predicts adaptive resolutions of subsequent stressors and life transitions. For example, whether future challenges to family functioning are viewed collectively and/or individually as unmanageable crises or as opportunities for growth may depend on competencies acquired and on success/failure experiences during prior life transitions and stressors. In addition, family development theorists now assume that there may be multiple pathways to adaptive and maladaptive outcomes for families experiencing similar stressors and life transitions.

THOUGHT DISTURBANCES

Thought, conscious and unconscious, serves the purposes of generating and monitoring communications, regulating activity, creating, proposing, and problem solving on both verbal and nonverbal levels. Thought disturbances can be observed in a continuum ranging in severity from the normally occurring breaks in attention to the pathological.

Some of the less serious thought disturbances are evidenced by hyperkinetic children whose attention is short-lived and whose tasks are interrupted by a seeming need to perform motor movement. Writers and composers also experience thought disturbances, such as blank periods during which, while all other normal functioning is intact, the ability to keep on with the writing or composing task seems impaired.

Frequently, psychoneuroses such as phobic reactions and anxiety reactions can be attributed to irrational ideas. Many of these irrational ideas are accompanied by poor self-statements. Other psychoneurotic thought disturbances are evidenced in obsessive thoughts where frequently occurring judgmental thinking interferes with normal functioning. Disputation of these thoughts can lead to clear logical thinking.

Psychosomatic symptoms are thought disorders that reflect the individual's inability to cope with anxiety and stress, which are transformed into physiological symptoms that can interfere with normal daily functioning as with many other psychoneurotic thought disorders.

Psychotic thought disturbances are usually accompanied by symptoms of *delusion,* where false beliefs of persecution or megalomania predominate, and *hallucinations,* where the organism generates its own stimulation in any or all of the sensory modalities. Although these thought disturbances are serious in their own right, they are generally attached to other types of pathological behavior, such as Delirium, Dementia, and Schizophrenia.

Delirium is a disturbance of varying severity of consciousness. The subject may be in any state from fully awake to coma, and there is evidence of disorders in cognitive function, thinking, and perception. Delirium is a result of cerebral dysfunction without any destruction of tissue and seems to originate from metabolic, chemical, or toxic disturbances. Delirium is generally transitional and disappears with the removal of the metabolic, chemical, or toxic elements.

Dementia syndrome, however, is a thought disorder related to cortical tissue damage evidenced by diminished intellectual capacity during clear consciousness. Personality, amnesiac, and disorientation changes occur as well. Here the fully alert patient does not grasp the present. Memory deficits and poor concentration are in evidence. Language deteriorates to the point of being childlike, and normal routine thoughts seem labored. Most disturbing is that many patients are aware of their cognitive difficulty and exhibit other secondary emotional disturbances.

Schizophrenia is an example of a psychogenic thought disorder. The schizophrenic's thought disorder seems to demonstrate a conscious sacrifice of physical and emotional life for some alternative "cocooned" existence for the perceived welfare of others. The thought disorder seems to direct an escape for survival as shown by a continual downward adjustment of functioning in an irrational struggle to stay alive. Withdrawal from social contact and emotional involvement occurs, as does regression toward a lower level of intellectual function. This exclusionary nihilistic thought disturbance exhibits itself in paranoid, catatonic, hebephrenic, and simple types.

THURSTONE SCALING

Thurstone scaling, also known as the method of equal-appearing intervals, is a technique devised by Louis L. Thurstone for constructing quantitative attitude measurement instruments. The first step in Thurstone scaling is to gather a large number of statements representing a wide range of opinions about the attitude object (e.g., capital punishment). Statements ranging from extremely negative through neutral to extremely positive are drawn from persons holding varying viewpoints or from the popular literature. These statements are then independently sorted by judges into 11 piles of equal-appearing intervals ranging from least favorable toward the object (1) through neutral (6) to most favorable (11). The median and semi-interquartile range (Q) of the judges' scores for each statement are then calculated, and statements with large Q values are discarded as ambiguous. The remaining statements are item-analyzed for internal consistency, and inconsistent statements are discarded as irrelevant.

What remains from this process is a pool of consistent,

unambiguous statements with scale values (median judges' scores) ranging from 1 to 11. The attitude scale itself is then constructed by including two or more statements from each of the 11 intervals on a questionnaire. Respondents check all of the statements with which they agree; the median scale values of the statements endorsed by respondents are their attitude scores. If the item pool is large enough, several parallel scales can be constructed, and the reliability of the attitude score can be determined.

Thurstone's technique is time-consuming and has been largely supplanted in popularity by newer techniques for developing measures of attitude. However, Thurstone scaling is a major step in the development of behaviorally anchored rating scales, mixed-standard rating scales, and weighted checklists for measuring work performance.

TIME-SERIES ANALYSIS

The statistical analysis of data that have been collected on a single unit (e.g., a person, family, or organization) at equally spaced time intervals (or in a continuous form) is a time-series analysis. Time-series methods are employed to describe the relationship between variables (e.g., biochemical measures in person A and the behavior of person A), to forecast (predict) future behavior, to describe the statistical nature of a process, and to estimate intervention effects.

A major difference between time-series and conventional methods is the nature of the designs to which they are applied. Time-series designs generally involve the collection of a large number of observations across time on a single participant or unit, whereas conventional designs generally involve only one or a few observations on a reasonably large number of participants. This difference in design characteristics often leads to a need for analytic methods that are not necessary in the analysis of most conventional designs. Time-series analyses, unlike most conventional analyses, are characterized by (1) formal evaluations of the assumption of independent errors, (2) analytic strategies to accommodate lack of independence if it exists, and (3) models that contain terms to describe how behavior changes across time.

Time-Series Domains

Approaches to time-series modeling generally fall into one of two major categories: time domain models and frequency domain models. Although there is a mathematical correspondence between the two, they represent different ways of conceptualizing the nature of time series, and they are designed to focus on different descriptive features of the data.

Time Domain Models

Time domain models contain parameters that are used to relate the behavior of process Y to other variables and to the history of process Y. For example, certain time domain models known as autoregressive moving-average (ARMA) models relate the current value Y_t of the time-series to earlier values of the series and to values of present and past random errors. A more general modeling approach that allows for the modeling of data that contain random trends is known as ARIMA (autoregressive integrated moving average). ARIMA models have become popular in the behavioral sciences; software for estimating the parameters of these models is widely available. However, the recommendation that sample size be reasonably large (a minimum of 50–100 is typical) before attempting such modeling has recently led to the development of alternative procedures for small samples. Some of these alternatives are closely related to conventional regression models.

The key issues in the selection of an adequate time-series analysis are the questions to be answered, the nature of the process that generates trend (if any), and whether the errors are independent. Some version of ARIMA or a simpler alternative model is usually chosen. Certain versions of time-series regression models are appropriate in some situations in which it was previously thought that ARIMA models were required. Because independence of the errors is assumed by conventional regression models, however, it is necessary to identify and model dependency among the errors if it exists.

If the dependency is not modeled, inferential tests on the parameters of the model, confidence intervals, and predictions based on ordinary regression methods will be distorted. Under some conditions the distortion can be severe. Hence, a preliminary step in the application of regression models to time-series data is to determine whether the errors of the model are approximately independent. A test of the hypothesis of independent errors is often carried out for this purpose.

If the errors are not independent, the model should be modified by either identifying and including in the model additional variables responsible for the dependency or accommodating the dependency by including terms in the model that describe it. The former should be attempted before the latter. When the latter approach is taken, several different types of coefficient are available to describe various types of dependency among the errors.

A typical time-series regression model contains parameters to describe systematic trends and other deterministic changes such as intervention effects across time as well as parameters to describe patterns among the errors of the model. A practical problem associated with models of this

type is that the time series should contain a minimum of about 50 observations if typical time-series regression methods (based on generalized least-squares) are used to carry out the analysis. Recently developed computer-intensive methods, however, provide adequate estimation with fewer observations.

Frequency Domain Models

Whereas a time domain model represents an attempt to explain current behavior of the series using time and other variables (including previous errors) as predictors, frequency domain models focus on breaking down the total series variation into basic frequency components. Frequency is related to the number of cycles of the response measure that occur during a defined period of time. Frequency domain methods (called harmonic analysis, periodogram analysis, and spectral analysis) provide a decomposition of the time-series variance into proportions that are explained by different cycles (if any).

TOILET TRAINING

The practice of toilet training children is the cause of a great deal of anxiety and frustration for parents and has resulted in debates among professionals. In *The Problem of Anxiety,* Freud (1936) suggested that inappropriate toilet training can result in lifetime trauma for the child. Others submit that the process of toilet training reinforces the self-centered nature of the young child. Wenar (1971) stated that "toilet training enhances the sense of power in the toddler whose thinking is naturally inclined to be omnipotent" (p. 76).

Whether one harbors anxiety over the prospects of toilet training one's child or views the process as a natural phenomenon that will, in time, run its course, the question remains: "What approach should parents take in toilet training their children?" Two psychologists who have examined toilet training philosophies and practices and have developed a strategy sensitive to the range of ideas are Azrin and Foxx. In their book *Toilet Training in Less Than a Day,* Azrin and Foxx (1974) developed a toilet training program that is responsive to the psychoanalytic emphasis on the possible effect of harsh toilet training on later personality, the medical knowledge about toilet training, the importance of Pavlivian learning, operant learning, imitation and social influence.

How and When

Azrin and Foxx (1974) suggest that there are four preliminary considerations to regard before commencing toilet training: age, bladder control, physical readiness, and instructional readiness. They submit that at age 20 months the child is usually capable of being toilet trained. They further submit that a child is ready for toilet training when the child demonstrates bladder control by strength of the urine stream as well as the quantity of urine eliminated. Readiness is also indicated when the child presents good finger and hand coordination (enough to pick up objects) and also is capable of walking independently. Finally, Azrin and Foxx suggest that toilet training readiness is indicated when the child can follow simple directions or imitate actions.

Once it is determined that a child is ready for toilet training, specific procedures can be followed that task-analyze the child's bowel and bladder elimination and the steps necessary for successful toilet training (Holmes, 2003).

Special Problems

Numerous articles have been written on subjects pertaining to toilet training problems. Ellis (1963) addressed the special needs of disabled individuals. Mowrer & Mowrer (1938) addressed nighttime wetting, and Wagner and Paul (1970) discussed bowel accidents. Whether one adheres to a psychoanalytic, behavioristic, or other viewpoint, there is consensus among theoreticians and practitioners that toilet training is a most important developmental milestone. Well-informed parents with a clearly defined approach will be most helpful to the child navigating the course of toilet training.

TOUCH THERAPY RESEARCH

Touch therapy or massage therapy is defined as manipulation of body tissues by the hands for wellness and the reduction of stress and pain. Its therapeutic effects derive from its impact on the muscular, nervous, and circulatory systems. Massage therapy sessions usually combine several techniques, including Swedish massage (stroking and kneading), shiatsu (pressure points), and neuromuscular massage (deep pressure). Oils are typically used, and aromatic essences are often added for further effect. The sessions also feature soft background music, usually classical or new age music.

The practice of massage has been in the world since before recorded time. The equivalent to the word *massage* can be found in many classic texts including the Bible and the Ayur-Veda. Hippocrates, as early as 400 B.C. talked about the necessity of physicians being experienced in the art of rubbing. Ancient records from China and somewhat later from Japan refer to massage therapy, and it was also widely used by other early cultures including Arabs, Egyptians, Indians, Greeks, and Romans. During the Renaissance, massage spread throughout Europe, and Swedish massage was developed early in the nineteenth century.

Based on existing research, clients who receive massage therapy are expected to show improved mood state and affect and decreased anxiety and stress hormone levels (salivary cortisol). These changes have been highly significant based on observations of the client, self-reports by the client, and saliva assays for cortisol. In addition, whenever the electroencephalogram is recorded, changes occur in the direction of heightened alertness. Longer term changes also measured in research have typically been evaluated after four weeks of treatment. These changes invariably include a decrease in depression (measured by self-report and elevated serotonin and dopamine levels), lower stress (as measured by urinary cortisol, norepinephrine, and epinephrine levels), improved sleep patterns (as measured by an activity watch), and enhanced immune function (an increase in natural killer cells). Changes have also been noted on clinical measures that are specific to different conditions or considered by clinicians to be gold standards for those conditions. For example, increases have been noted in pulmonary functions including peak air flow for children with asthma, and decreased blood glucose levels have been reported for children with diabetes following a month of bedtime massages from parents. Another example is a significant increase in weight gain in premature infants given three massages per day over a 10-day period. These changes are unique to these conditions and would not be expected to occur generally across medical conditions.

Although the primary indications have been for wellness and a reduction of stress and pain, there are many other ways in which massage therapy is clinically useful, including the following: (1) pain reduction during painful procedures such as childbirth labor, and massage therapy prior to debridement for burn patients; (2) pain reduction in chronic pain conditions such as juvenile rheumatoid arthritis, fibromyalgia, premenstrual syndrome, lower back pain, migraine headaches, and carpal tunnel syndrome; (3) alleviation of depression and anxiety, such as in bulimia, anorexia, and chronic fatigue; (4) stress reduction including job stress and separation stress; and (5) immune disorders including HIV and breast cancer following an associated increase in natural killer cells, which are the front line of the immune system and ward off viral cells and cancer cells, as well as for the autoimmune conditions already mentioned, including diabetes and asthma. Although some therapists have warned of contraindications for massage, there is virtually no research supporting concerns such as infectious or contagious skin conditions, high fever, scar tissue, varicose veins, and tumors.

Many massage therapists are located in private clinics in the community, spas, workout clubs, hair salons, hotels, airports, and even sometimes at car washes. Unfortunately, although massage therapy used to be routinely practiced in hospitals (as recently as the 1950s), it is rarely seen in hospitals today. The costs are relatively low ($1 per minute is the going rate), and the therapy has been shown to be cost-effective. For example, $4.7 billion per year could be saved in medical costs if all premature infants were massaged. That figure derives from 470,000 infants who are born prematurely each year being massaged and discharged 6 days early at a hospital cost savings of $10,000 per infant. Similarly, using senior citizen volunteers as therapists for infants has been cost-effective and has resulted in lower stress hormones and fewer trips to the doctors' office following one month of the therapists' massaging the infants. Similar cost-effective figures are likely to emerge for other

conditions because they too benefit from the lower stress hormones (cortisol), enhanced immune function, more infrequent illness, and greater wellness resulting from massage therapy.

TOWER OF HANOI PROBLEM

The Tower of Hanoi is a classical puzzle applied in the psychology of problem solving and cognitive skill learning. In the standard version, it consists of three vertical wooden pegs and a variable number of wooden disks, usually three to six, with different diameters. The disks have a hole in the middle and are stacked on the left peg in the order of diameter, the largest at the bottom. The task is to transfer the disks to the right peg with a minimum of moves. Disks may be moved only from one peg to another. Any peg may serve as a temporary target for any disk. Only one disk may be moved at a time, and larger disks must not be placed above smaller ones. Performance is measured by the number of moves, the time required to complete the task, or both. In addition, different types of errors can be classified and assessed. The minimum number of moves is $2^n - 1$, where n is the number of disks (e.g., 31 for the five-disk version). Approximate mean performances on the first attempt are 22 moves and two minutes for the four-disk and 64 moves and 10 minutes for the five-disk version. In aged subjects, mean baseline performance declines.

The problem can be broken down to n similar subgoals (i.e., moving the next-largest disk to the right peg). Before one of these key moves is possible, the corresponding disk is isolated (alternately) on the left or middle peg, and all smaller ones are stacked on the remaining peg. Thus goal and subgoals, as well as lower-order subgoals, are self-similar and require an equivalent strategy. At any stage, it is crucial to decide, by counting disks, where to make the first move; otherwise, the process of unloading can lead to a blockade of the current target peg. Naive subjects tend to apply less efficient, ad-hoc strategies or the trial-and-error approach.

The Tower of Hanoi problem requires visuospatial abilities (i.e., visual imagery and visuospatial working memory) for the mental manipulation of disk configurations. It also requires spatial long-term memory for the retention of move sequences. In normal subjects, a measure of spatial ability has, among several cognitive variables, been found to correlate highest with the time required to solve the four-disk problem. In amnesiac patients, performance was highly correlated with residual declarative memory capacity (Schmidtke, Handschu, & Vollmer, 1996). It is furthermore assumed that performance depends on frontal lobe or executive function. Patients with lesions to the frontal lobe of the brain were reported to require more time and moves to solve the Tower of Hanoi, as well as related problems derived from it. The deficit of these patients has been assigned to deficits of planning and to an inability to resolve goal-subgoal conflicts (Goel & Grafman, 1995; Morris, Miotto, Feigenbaum, Bullock, & Polkey, 1997). The Tower of Hanoi problem is sensitive but not specific to prefrontal dysfunction. In other patient groups, subnormal performances have been attributed to impairments of spatial memory or strategy formation. Since the problem involves several cognitive capacities, its value as a neuropsychological test is limited.

Repeated execution of the problem leads to improvement of performance. In the four-disk version, many normal subjects achieve a ceiling level of performance within few attempts. Higher numbers of disks require considerably more trials. The rules and basic procedure (i.e., moving small stacks of disks from one peg to another) are quickly proceduralized. Perfect performance requires explicit (declarative) knowledge of the strategies mentioned earlier. Before this level is achieved, relapses (i.e., markedly worse single performances) occur even at advanced stages of learning. Procedural learning of the Tower of Hanoi problem thus involves both declarative and nondeclarative components, whose exact contribution is difficult to determine. The problem has also been employed as a paradigm for the study of skill learning (procedural learning) in cognitively impaired subjects, specifically in patients with amnesia and basal ganglia disease. Amnesiac patients, who may not remember having encountered the problem before, usually make considerable progress over trials. However, their learning is slowed in comparison to normal subjects. This is likely due to their deficient declarative memory for strategies, as well as to deficits of planning and other cognitive capacities that typically go along with amnesia. Word fluency, applied as a measure of prefrontal function, has been found to correlate with measures of learning of the Tower of Hanoi problem (Schmidtke et al., 1996). Negative effects of age on the rate of learning have inconsistently been shown.

Variants of the Tower of Hanoi problem have been developed to study planning and problem solving in normal subjects, psychiatric patients, and patients with organic brain damage. As an alternative to moving the whole stack of disks to another peg, the defined goal can be a rearrangement of disks from one given configuration to another. Isomorphs of the problem (e.g., the Monster Prob-

lems) involve an analogous problem space and set of rules but different outer appearance (Kotovsky, Hayes, & Simon, 1985). The Tower of London (Shallice, 1982) has been applied in a number of versions. It is thought to depend more on planning and less on visuospatial abilities. Originally, it involves three beads of different colors and three pegs of different lengths that can carry one, two, and all three beads, respectively. From variable starting positions, the beads have to be rearranged to patterns shown on cards on which the number of moves needed is also indicated. Difficulty varies from one to five moves. Computerized versions use colored balls and touch-sensitive screens. In normal subjects, functional imaging studies of the task showed, among other areas, activation of the dorsolateral prefrontal bilaterally, the lateral parietal cortex bilaterally, and the left anterior cingulate gyrus (Baker et al., 1996).

TOXICITY AND NEUROPROTECTIVE EFFECTS OF CARBON MONOXIDE: CONSEQUENCES TO SUICIDE AND SURVIVAL

Introduction

Previous work has focused mainly on the toxic physiologic effects of inhaled carbon monoxide (CO) gas arising from exogenous sources. CO toxicity is often associated with suicide attempts, and inhaling motor vehicle exhaust fumes is a leading cause of poisoning deaths in America. Recently, it has been demonstrated that CO can be produced endogenously through the actions of heme oxygenase (HO), an enzyme that generates CO by degrading heme. The search for a specific enzyme that can generate CO was stimulated by the finding that nitric oxide (NO), another endogenously produced biologically active gas, can be enzymatically obtained through nitric oxide synthase. Low concentrations of endogenously generated CO appear to have a neuroprotective function, whereas higher levels achieved by inhaling exogenous CO produce severe neurotoxicity.

Endogenous Formation of Carbon Monoxide by Heme Oxygenase

Heme oxygenase degrades heme, which by opening the porphyrin ring generates CO. Heme in the cell is a key component of many essential enzymes (e.g., myoglobin, catalase, glutathione peroxidase, cytochrome, soluble guanylate cyclase, superoxide dismutase, nitric oxide synthase, etc.), and regulation of the free cellular levels is tightly controlled. Heme oxygenase activity can be modulated either by changing the expression levels or via posttranscriptional modifications. CO is a gas that can travel freely throughout intracellular and extracellular compartments. The literature regarding the physiologic role of CO is complex, and many controversies have yet to be resolved (Alkadhi, Al-Hijailan, Malik, & Hogan, 2001; Linden, Narasimhan, & Gurfel, 1993; Maines, 1996; Meffert, Haley, Schuman, Schulman, & Madison, 1994; Poss, Thomas, Ebralidze, O'Dell, & Tonegawa, 1995; Verma, Hirsch, Glatt, Ronnett, & Snyder, 1993).

Two isoforms of HO have been distinguished and well studied (Doré et al., 2002; Ewing & Maines, 1997; Shibahara, Muller, Taguchi, & Yoshida, 1985). HO1 was the first to be isolated (Shibahara et al., 1985). It is an inducible enzyme that is concentrated in tissues such as the spleen and liver. On the other hand, HO2 is constitutive and has been suggested to be the neuronal isoform (Rotenberg & Maines, 1990). HO2 is most concentrated in the brain, accounting for the vast majority of HO activity in the brain (Doré et al., 1999, & Doré et al., 2002). HO1 is inducible in glia cells by hyperthermia (Ewing, Haber, & Maines, 1992), in Alzheimer's disease (Schipper, Cisse, & Stopa, 1995), in global ischemia (Takeda et al., 1996), in transient ischemia (Doré et al., 1999), in subarachnoid hemorrhage (Kuroki, Kanamaru, Suzuki, Waga, & Semba, 1998), and by experimentally injected lysed blood into striatum and cortex (Matz, Weinstein, & Sharp, 1997). Very few studies have been able to detect significant changes in the HO2 protein levels after different stimuli, and modulation of its activity could be a key element to understanding its function in the brain (Doré et al., 2002). One study demonstrated that mice with a genetic deletion of HO2 had infarct volumes twice those of normal control mice after 1 h of middle cerebral artery occlusion and 23 h reperfusion (Doré et al., 1999). Taken together, these results suggest that increasing intraneuronal HO activity provides neuroprotection. Modulation of HO2

activity may be crucial in neuron survival. HO2 might function either as a detoxifying agent of heme (a pro-oxidant), which is released from heme-containing proteins or from extravasation of blood/hemoglobin, or by generating CO, which could have physiologic neuroprotective capabilities.

Effects of Carbon Monoxide on Brain Functions

The affinity of CO for several proteins is generally lower than the affinity of nitric oxide for the same proteins; however, the longer half-life of CO could be a key factor in modifying several key enzymes containing a heme moiety. At a cellular level, physiologic levels of CO generated from degradation of intracellular heme are likely to have biologic actions on several heme-containing proteins. For example, CO may act as a vasodilator by binding to soluble guanylate cyclase and modulating its activity, as discussed later (Maines, 1996; Verma et al., 1993). CO can also act by opening calcium-activated potassium channels (KCa^{2+} channels; Wang & Wu, 1997).

CO has also been reported to have specific anti-inflammatory and antiapoptotic effects (Brouard et al., 2002; Otterbein et al., 2003). The mechanism of protection against apoptotic-like cell death by which CO would act has been suggested to be mediated through the activation of a transduction pathway involving the p38 kinase (Otterbein et al., 2000). This cascade has been previously demonstrated in endothelial cells. When these cells are exposed to inflammatory stimuli, they become activated through the expression of inflammatory proteins. Through the generation of protective genes (heme oxygenase would be among them), these cells are protected against the effects of triggering the apoptotic cascade (Otterbein et al., 2003). Through this process, CO would be generated and would act as a cytoprotective molecule that would limit the deleterious effects of the triggered inflammatory process (Otterbein et al., 2000, 2003).

By competing with sites that generally bind NO, CO may lead to an increase in free levels of NO. By itself, NO is a potent activator of guanylate cyclase and can participate in vasodilation. On the other hand, NO is very reactive and could stimulate the production of related free radicals, which can cause cellular damage often observed as nitrotyrosylation of proteins. Damage due to the generation of free radicals can be either to the cell or the blood vessels, depending on where NO is being dissociated from heme. Thus, even at relatively low concentrations, CO can produce oxidative stress and subsequent cell death. Using animal models, oxidative damage in rats has been observed with CO levels at 1,000 ppm for 40 minutes or as little as 50 ppm for 1 hour. These exposures are sufficient to cause an increase in nitrotyrosine and nitrosylated proteins (Ischiropoulos et al., 1996; Thom, Fisher, Xu, Garner, & Ischiropoulos, 1999). It was suggested that since CO does not modify the activity of the enzyme nitric oxide synthase, a total decrease in NO bound to heme proteins of the platelets would be the possible origin of the free NO. Interestingly, it's been reported that in rats, as little as 50 ppm of CO ventilation for 1 hour was sufficient to allow detection of nitrosylation (Thom et al., 1999). Even low levels of CO of sufficient duration are enough to trigger a cascade generating toxic free radicals (Thom et al., 2000).

Specific brain regions (especially central white matter) are differentially sensitive to damage by CO (Kindwall, 1996). According to the dose and duration of CO exposure, apoptotic and necrotic neuronal death similar to hypoxia-induced ischemia becomes particularly evident in the globus pallidus, hippocampus, cerebral cortex, and cerebellar Purkinje neurons (Piantadosi, Zhang, Levin, Folz, & Schmechel, 1997). The specific vulnerability of these brain regions to CO toxicity could be due to damage to the endothelial walls or directly by transendothelial CO diffusion. Further investigations are necessary to clarify the cellular effect of physiologic levels of CO and its toxic levels at supra-physiological concentrations.

In contrast, NO and CO have been known to play a significant role in establishing memory, especially in regard to long-term potentiation (LTP). They are in a unique family of gas neurotransmitters; these gases cannot be stored in synaptic vesicles and are thus believed to be generated on demand. As mentioned earlier, heme oxygenase is a specific enzyme that generates CO. HO2 is present in high concentrations mainly in the testes and in the brain. In the nervous system, it accounts for the majority of HO action and is discretely localized in neurons and also interestingly colocalized tightly with the guanylate cyclase enzyme (Verma et al., 1993). By generating CO, HO is likely to modulate levels of cyclic GMP (cGMP) by affecting enzyme activity. The use of general HO inhibitors has implicated a role for HO/CO in establishing LTP (Linden et al., 1993), although the specific role of CO in this pathway remains to be firmly established. Interestingly, the authors have demonstrated a trend toward a decrease in HO2 expression levels in ages rats compared to young rats. (Law et al., 2000) When the aged rats are split into two groups based on the presence or absence of cognitive impairment, the impaired rats have higher HO2 levels, suggesting a possible compensatory mechanism. This could possibly help restore cognitive function by increasing the HO2 expression (Law et al., 2000).

Inhalation of Exogenous Carbon Monoxide

CO is known to be toxic, and the inhalation of high concentrations can cause death. CO is an odorless, colorless, and tasteless product of incomplete fuel combustion. Accidental CO poisoning at home occurs more frequently during the winter and is generally due to defective or improper household appliances that use combustible fuel, such as gas, oil, coal, kerosene, or wood, as well as to poor ventilation. Accidental CO poisoning can also occur in other locations as reported in indoor ice-skating rinks, with outdoor tractors, or

on motorboats (*JAMA,* 1996; Silvers & Hampson, 1995). CO detectors installed in homes have significantly reduced the incidence of CO poisoning.

Some CO toxicity is accounted for by the fact that CO saturates hemoglobin and impairs its ability to transport oxygen. The affinity of CO to Hb is approximately 200 times higher than that to oxygen. During CO inhalation, the amount of CO bound to heme groups on the hemoglobin increases, generating carboxy-hemoglobin, which consequently decreases the amount of oxygen being carried to tissue and brain. Hypoxia is then likely to affect normal cellular function. The brain has a very high metabolic rate of O_2 consumption, and impaired blood flow causes a rapid loss of consciousness. The brain has a complex array of mechanisms that limit damage following even the smallest changes in tissue oxygenation. During hypoxic states, arteriolar dilation occurs, improving O_2 transport. In the case of CO hypoxia, changes in cerebral blood flow are strictly correlated to the amount of COHb. In addition, by binding on heme-containing proteins, such as the cytochrome system, CO is likely to impair electron transport and also affects leukocytes, platelets, and endothelium, which can also generate a cascade of events leading to oxidative stress damage (Hardy & Thom, 1994).

Death from the inhalation of CO is a commonly used method for people attempting suicide. In newer model vehicles that have catalytic converters, less CO is released from the exhaust system. The catalytic converter was introduced in the 1970s and had a CO emission rate as low as 6g/minute. By 1989 the average new car emitted CO at about 0.22g/min. With the recent introduction of three-way catalytic converters, the reduction in CO emissions is close to 99%. The lower CO exposure during suicide attempts has led to a modified clinical symptom presentation (Vossberg & Skolnick, 1999). Patients are more likely to remain alive after hours of exposure, compared to death within 30 minutes in a closed environment with a vehicle without a catalytic converter.

Recovering patients are likely to have been exposed to a lower concentration of CO but for a longer period. Nonspecific symptoms of CO exposure include headache, nausea, fatigue, mental confusion, clumsiness, impaired judgment, stupor, and coma. Neurologic consequences of CO exposure include traditional cerebrovascular malfunctions, peripheral neuropathies, acute psychosis, cortical blindness, and memory problems (Choi, 1983). Neuroimaging studies indicate that the perivascular zone is a primary target for CO toxicity. Secondary hemorrhagic necrosis may generate focal pathology (Silverman, Brenner, & Murtagh, 1993). Most of the neurologic damage has been reported to occur within the first 6 hours of acute CO exposure, although delayed neurologic complications (e.g., disorientation, bradykinesia, gait disturbances, aphasia, aprasia, incontinence, and cogwheel rigidity) are evident up to 40 days postexposure; (Hardy & Thom, 1994). Close monitoring and follow-up of these patients is essential for optimal recovery.

Summary

In conclusion, at high concentrations, CO can produce serious brain damage. However, at physiologic concentrations, CO is emerging as a unique molecule with beneficial effects. More studies are necessary to understand the complex function of this simple diatomic gas. Once considered to be similar to an inert gas, it now appears that CO has multiple biologic actions. Additional study of this molecule should aim at further exploring the positive effects of CO while gaining a better understanding of treatment following sublethal accidental or intentional exposure.

TRAIT PSYCHOLOGY

Trait psychology is an approach to the theory and measurement of personality relying heavily on the concept of *trait* as a fundamental unit. Traits are defined in various ways. At the simplest level, they are seen as relatively enduring descriptive characteristics of a person. At a somewhat broader level, traits are defined as predispositions to behavior that are both enduring (i.e., having temporal consistency) and wide ranging (i.e., having cross-situational consistency). Gordon Allport asserted that traits also had a physiological basis. Allport also differentiated between common traits, found at some strength in all persons in a given culture, and unique traits, peculiar to an individual. The strongest, most pervasive dispositions within a person, he called cardinal traits.

A term frequently associated with trait is *type.* A trait is a single continuous dimension of personality, but a type is a more complex pattern of characteristics that serves as a model for categorizing people. Early in this century, Carl Jung identified sets of opposite personality types with extraverted versus introverted attitudes, and intuiting versus sensing and thinking versus feeling functions, now measured by the Myers-Briggs Type Indicator. Hans Eysenck and most other trait theorists see personality as organized hierarchically with major predispositions encompassing a set of related traits; for instance, the extraverted type includes traits such as sociability, impulsiveness, and activity.

Another term often contrasted with trait is *state,* which refers to a temporary condition, such as a mood, whereas trait refers to a long-range predisposition. In testing for

state anxiety, for instance, C. D. Spielberger asks whether the person feels upset now; in testing for the corresponding trait, he asks if the person is generally, often, or constantly upset.

In many personality theories, traits occupy an important position as the basic units inferred from behavior. Several theorists use a trait-and-factor model; that is, they build systems empirically by factor analyzing a variety of items to produce basic scales or a variety of tests to produce higher level factors. The major personality theorists of this kind are Raymond Cattell, Eysenck, and J. P. Guilford. Each has developed tests for constructs they see as basic traits.

Two issues regarding traits are particularly prominent. The first is the question of the number and kind of traits. Instead of Cattell's 16 factors for questionnaire data, Eysenck identified three: extraversion, emotionality (neuroticism), and psychotism. Other widely used dimensional systems emphasizing interpersonal relations have identified two major axes—friendliness-hostility and dominance-submission—with many degrees of variation between them arranged in a circle. These two axes parallel the features frequently mentioned in organizational psychology—the socioemotional versus the task-oriented aspects of roles.

The other significant issue is the question of the cross-situational consistency of traits. The early work of Hartshorne and May temporarily shattered the belief in consistency of such traits as honesty by demonstrating that children who cheat on an examination do not necessarily lie or cheat in other circumstances. Yet intuitively we feel that people are consistent. By 1972 Eysenck had concluded that the trait position had been upheld and accepted. However, about that time, the much greater attention to the environment and the rise of behavioral psychology led to further attacks on traits, especially by W. Mischel. However, Mischel and others subsequently have recognized that there is considerable consistency among some characteristics. Mischel and P. K. Peake noted that temporal and situational consistency should be separated. The former is high and the latter low in reliability. Using a cognitive prototypical approach, they proposed a resolution of the dilemma, saying that the perception and organization of personality consistencies depend on identifying the key features (the prototypes, or best examples of a characteristic) in personality rather than on behavioral-level consistency in situations.

TRANSCENDENTAL MEDITATION

Various types of meditation have been practiced for over 2,500 years. Many Eastern cultures have included forms of meditation as an important part of their religious and spiritual enrichment (e.g., Zen, yoga). More recently, the West has taken an interest in the practice of transcendental meditation (TM) as taught by Maharishi Mahesh Yogi. It is promoted as a means to help increase energy, reduce stress, and have a positive effect on mental and physical health. The actual practice of TM involves sitting upright, with the eyes closed, and silently repeating a mantra whenever thoughts occur. The meditation is said to be effortless, enjoyable, and relaxing. The individual is instructed to meditate for 20 minutes in the morning before breakfast and 20 minutes in the evening.

Research on Transcendental Meditation

Numerous research studies have investigated the efforts of TM on physiological and psychological processes. These studies are summarized in the following.

Physiological Effects

In 1970 Wallace reported that a number of physiological states occurred during the practice of TM (e.g., significant decrease in respiration rate, heart rate, oxygen consumption, and skin conductance). West (1979) noted that Wallace's findings were supported by several other researchers (i.e., a decrease in heart rate: Dhanaraj & Singh, 1976; a decrease in respiration rate and oxygen consumption: Treichell, Clinch, & Cran, 1973; and a decrease in skin conductance: Walrath & Hamilton, 1975).

West (1980) also noted that TM has a significant effect on electroencephalogram (EEG) readings:

1. During the beginning of meditation, alpha amplitude increases, and alpha frequency may slow by 1–3 Hz.
2. During the middle of the meditation, trains of theta rhythms occur, often intermixed with alpha.
3. During deep meditation, bursts of high-frequency beta of 20–40 Hz can occur.
4. At the end of meditation, alpha may continue even while the eyes are open.

It is thought that EEG readings may be useful in monitoring the individual's response to meditation. Those with atypical EEG readings may need to obtain additional TM instruction or may not be able to use it effectively.

Research has attempted to compare TM to napping, eyes-closed rest, and contemplation meditation in terms of physiological and cognitive ability. Wallace (1999) noted that regular practitioners of TM (as compared to those who close their eyes and rest) had significantly more changes in the autonomic and central nervous system associated with EEG alpha coherence patterns.

Orme-Johnson (2001) compared TM, napping, and contemplation meditation to a no-treatment control group in

terms of seven cognitive tasks associated with the following instruments (Test for Creative Thinking-Drawing Production, Constructive Thinking Inventory, Group Embedded Figures Test, State and Trait Anxiety, Inspection Time, and Culture Fair Intelligence Test). Results showed TM practitioners to be superior on seven out of seven compared to the control. Contemplation meditation was superior in two of seven areas of cognitive functioning (Inspection Time and Embedded Figures). Napping did not improve cognitive functioning on any of the seven cognitive variables as compared to the control group. In addition, the TM group was superior to the contemplation group on five variables.

Education

The Science of Creative Intelligence (SCI) is an educational program based on the philosophical foundations of TM (Thuermer, 2002). It is a consciousness-based educational approach that suggests that intellectual functioning can be enhanced by daily meditation (e.g., stress reduction and creative problem solving).

Personality

Transcendental meditation appears to have a positive effect on personality functioning and well-being. For example, Nystul and Garde (1977) found that individuals practicing TM for a mean of 3 years had significantly more positive self-concepts on the Tennessee Self-Concept Scale in terms of total positive, identity, self-satisfaction, personal self, and moral ethical self. TM has also been associated with increases in self-control, happiness, and self-actualization and decreases in psychopathology, such as psychosis, anxiety, and depression (Seeman, Nidick, & Banta, 1972; Hjelle, 1974; Nystul & Garde, 1977, 1979).

Therapy

West (1979) noted that studies have shown TM practitioners to stop or to decrease dramatically the usage of nonprescribed drugs (e.g., Shafi, Lavely, & Jaffe, 1975). Transcendental meditation has also been used as an adjunct to psychotherapy. For example, Vahia, Doongaji, Kapoor, Ardhapurkar, and Ravindra (1973) found that yoga and meditation significantly reduced the anxiety of psychoneurotics. Meditation procedures similar to TM have also been used in the treatment of obesity (Berwick & Oziel, 1973) and claustrophobia (Boudreau, 1972).

The Dropout Phenomenon

Over 50% of the individuals who begin TM stop practicing after 1 year of training (Zuroff & Schwarz, 1980). There are several explanations for this high dropout rate. Otis (1974) noted that a significantly high percentage of neurotic individuals are attracted to TM. They appear to have high expectations and are looking for a quick solution to complicated psychological problems. When TM does not provide them with the answers, they tend to stop practicing it. Nystul and Garde (1979) also found that individuals who stopped practicing TM had significantly more of the characteristics of psychosis than did those who practiced TM regularly.

There may also be some dangers associated with TM that could account for the high dropout rate. For example, TM has been known to cause severe depression, attempted suicide, and schizophrenic breaks (Lazarus, 1976). The negative effects of TM most often result with individuals who overmeditate for 3 hours or more at a time (Carrington, 1977). People who do not overmeditate also may find the practice of TM too stressful. As one meditates, many suppressed and repressed thoughts and feelings may be brought into awareness. One may become overwhelmed by these thoughts, thus resulting in a pathological reaction.

Violence Prevention

A somewhat controversial area of research investigated the potential of TM on reducing violence in society. Hagelin et al. (1999) conducted an innovative study that involved 4,000 individuals practicing TM in Washington, DC, from June 7 to July 30, 1993. It was concluded that the influx of individuals practicing TM reduced collective levels of homicide, rape, assaults, and robberies by 15.6%, though definitive conclusions could not be reached. Results also suggested that a permanent group of 4,000 individuals practicing TM could potentially promote a long-term reduction in serious crime.

TRANSSEXUALISM

Terminology

The term *transsexual* has existed in the professional literature since the early 1920s (Hirschfeld, 1923). In the currently widely used psychiatric classification system of the *Diagnostic and Statistic Manual of Mental Disorders,* fourth edition (*DSM-IV;* American Psychiatric Association, 1994), the term *transsexualism* was replaced by gender identity disorder (GID). This term is used for individuals who show a strong and persistent cross-gender identification and a persistent discomfort with their anatomical sex as manifested by a preoccupation with getting rid of one's sex characteristics or the belief that one was born the wrong sex.

Development

Individuals may develop a gender identity disorder at the age of 2 or 3 years, but not all children with GID turn out to be adult transsexuals. It is estimated that about 10–20% will appear to be transsexual after puberty (Cohen-Kettenis, 2001; Zucker & Bradley, 1995).

Both environmental factors and biological factors have been put forward to explain atypical gender development. Children with and without GID indeed appear to differ in terms of parental psychopathology. They also differ in child-related factors such as temperament and appearance. Although retrospective studies in adult transsexuals have shown differences in recalled child-rearing patterns between transsexuals and normative groups (e.g., warmth, rejection), these parental behaviors might have been a consequence of the child's gender problem rather than a determinant (for reviews see Cohen-Kettenis & Pfäfflin, 2003; Zucker & Bradley, 1995). The specific mechanisms leading to GID clearly remain to be elucidated.

Potential biological determinants of transsexualism have been found in studies among subjects with an abnormal pre- and perinatal endocrine history. They seem to be at higher than normal risk for GID (Zucker, 1999). Furthermore, a sexually dimorphic brain nucleus (the BSTc) of transsexuals appeared to be completely in the size range of the opposite sex (for reviews see Cohen-Kettenis & Pfäfflin, 2003; Zucker & Bradley, 1995).

Prevalence

Prevalence estimates of transsexualism among the population aged 15 years and above are based mainly on the number of transsexuals treated at major centers or on responses of registered psychiatrists to surveys concerning their number of transsexual patients within a particular region. The numbers vary widely across studies. The estimated prevalence now varies between 1:10,000–40,000 men and 1:30,000–100,000 women (Bakker, van Kesteren, Gooren, & Bezemer, 1993; Weitze & Osburg, 1998).

Treatment

As psychotherapy is inadequate for a crystallized cross-gender identity, sex reassignment is considered to be the best treatment option. The recommended procedure in the Standards of Care of the International Harry Benjamin

Gender Dysphoria Association (an international professional organization in the field of transsexualism; Meyer et al., 2001) is to come to the final, surgical, decision in phases. First, a diagnosis is made on formal psychiatric classification criteria. Then, one's capability to live in the desired role and the strength of the wish for sex reassignment is tested during the real-life experience. The social role change during the real-life experience is usually supported by hormonal therapy. Surgery changes the genitals and other sex characteristics only after a successful real-life experience.

As a result of hormonal therapy in male-to-female transsexuals (MFs), bodily hair growth diminishes drastically, as do penile erections, sexual appetite, and upper body strength. In addition, female sex characteristics develop, such as breasts and a more female-appearing body shape due to a change of body fat around the waist, hips, shoulders, and jaw. Sometimes, facial hair removal techniques are necessary, and speech therapy is necessary for a successful demasculinization. In female-to-male transsexuals (FMs), androgens are used for the induction of male body features, such as a low voice, facial and body hair growth, and a more masculine body shape.

In MFs a vagina is constructed and, in cases of unsatisfactory responsiveness of breast tissue to estrogens, a breast enlargement is performed. In FMs breast reduction takes place in all cases. Because phalloplasty is still in an experimental phase, some FMs prefer to have a neoscrotum, testical prosthesis, and meatidoioplasty, in which the enlarged clitoris (due to hormone therapy) is transformed into a microphallus (Hage & Mulder, 1995).

Results of Sex Reassignment

Pfäfflin and Junge (1998) extensively reviewed 79 studies between 1961 and 1991 that evaluated the effects of reassignment. Since 1991, several more follow-up studies have appeared (for a review, see Cohen-Kettenis & Pfäfflin, 2003). Satisfactory results are reported in 87% of the MFs and 97% of the FMs. FMs usually fare better than their MF counterparts. Negative results, such as severe postoperative regrets to the point of returning to the original gender role, are estimated to be around 1%. From the follow-up studies one may infer that the currently employed, often extensive, diagnostic methods are sufficiently strict.

TRANSVESTISM

In the psychosexual disorder of *transvestism,* there is recurrent and persistent cross-dressing by a heterosexual male for the purposes of his own sexual arousal. That is, the man achieves sexual satisfaction simply by putting on women's clothing, although masturbation (and heterosexual intercourse) is often engaged in once the individual is attired in female garb. Although anxiety, depression, guilt, and shame are often associated with the desire to cross-dress, the transvestite continues to do so because of the considerable satisfaction derived from the practice.

While transvestism is a comparatively rare disorder, some research has been conducted on it. To illustrate, it has been found that the typical transvestite is probably married (about two thirds are), and if married, has children (about two thirds do). Moreover, the overwhelming majority of transvestites assert that they are exclusively heterosexual, and the most common transvestic behavior consists of cross-dressing at home in secret. Concerning their psycho-

logical makeup, transvestites as a group are no more neurotic or psychotic than matched control groups, although they do tend to be more controlled in impulse expression, more inhibited in interpersonal relationships, more dependent, and less involved with other people. More than three fourths of transvestites consider themselves to be a different personality when cross-dressed, perhaps experiencing in female clothing a significant facet of their psychological makeup that cannot otherwise be expressed.

Finally, transvestism needs to be distinguished from transsexualism, fetishism, and homosexuality because each of these is sometimes confused with this disorder. In *transsexualism* there is a chronic sense of discomfort and inappropriateness about one's anatomic sex, a persistent wish to be rid of one's own genitals, a desire to live as a member of the opposite sex, and never any sexual arousal associated with cross-dressing; the great majority of transvestites consider themselves male, and erotic arousal is centered on dressing in women's clothing. Although articles of female clothing are involved in both *fetishism* and transvestism, fetishists do not dress in them, whereas transvestites do. Finally, while some male *homosexuals* may occasionally cross-dress to attract another male or to masquerade in theatrical fashion as a woman, the act itself is not sexually stimulating for them. For transvestites, the cross-dressing itself is the focal point of sexual stimulation, and no attempt is made to invite the sexual attention of other males.

TRAUMA

Definition

Trauma can be conceptualized as both an event and a reaction. A traumatic event is one in which an individual experiences actual or threatened serious injury or death (American Psychiatric Association [ApA], 2000). Examples of traumatic events include military combat, sexual assaults (e.g., rape or child sexual abuse), interpersonal physical assaults (e.g., a mugging), natural or manmade disasters, terrorist attacks, and motor vehicle accidents (ApA, 2000; Kessler, Sonnega, Bromet, Hughes, & Nelson, 1995).

In addition to being an event, trauma can also be conceptualized as a reaction. An individual's response to a traumatic event often involves intense emotions, such as fear, helplessness, or horror (ApA, 2000). The individual's emotional response and subjective appraisal of the situation are an integral part of the definition of trauma. Thus, witnessing an event in which another individual is seriously injured or killed or learning about the violent death or injury of a close friend or family member may also be considered traumatic (APA, 2000).

Difference Between Stress and Trauma

It is important to differentiate between stress and trauma. Stress is a reaction to events in the environment (Resick, 2001). These environmental events (stressors) can be negative, such as a hassle at work, or positive, such as getting married. Individuals experience stress also in response to more serious problems, such as divorce or financial strain. Although these experiences are difficult, they result in stress reactions, not trauma reactions (Resick, 2001).

Psychological Sequelae to Trauma

Posttraumatic Stress Disorder

In order to be diagnosed with posttraumatic stress disorder (PTSD), an individual must experience a traumatic event in which he or she feels threatened with death or serious injury and experiences intense emotions, such as fear, helplessness, or horror. Exposure to such a traumatic event results in three clusters of pathological symptoms: reexperiencing, avoidance, and arousal (ApA, 2000). The trauma may be reexperienced through intrusive memories, nightmares, flashbacks, or psychological or physiological distress at reminders of the trauma. The avoidance cluster of symptoms includes avoidance of any stimuli reminiscent of the trauma (from places and people to subjective thoughts and feelings), as well as a general numbing of responsiveness (e.g., feeling detached from others or having a restricted range of affect). Finally, individuals with PTSD suffer from arousal symptoms such as insomnia, irritability, difficulty concentrating, hypervigilance, and an exaggerated startle response. To meet diagnostic criteria, these symptoms must endure for at least one month and must cause problems in life functioning.

Acute Stress Disorder

Whereas PTSD can first be diagnosed 1 month after exposure to a traumatic event, acute stress disorder (ASD) can be diagnosed as soon as 2 days after exposure (ApA, 2000). Similar to PTSD, ASD results from exposure to a traumatic event in which the individual feels threatened by death or serious injury and experiences intense emotions, such as fear, helplessness, or horror. In addition, the individual must experience some dissociative symptoms either during or after the event. Dissociative symptoms include feeling emotionally numb or detached from the situation, feeling in a daze, and having the sense that the experience is somehow unreal or that the experience is not happening (ApA, 2000). Similar to the PTSD diagnosis, ASD also involves reexperiencing, avoidance, and arousal symptoms. The symptoms must cause the individual distress or cause impairment in functioning.

Adjustment Disorder

Adjustment disorder can be diagnosed within 3 months of exposure to a traumatic event for individuals reporting

more distress than would normally be expected from the stressor. This distress is manifest through emotional or behavioral changes that cause significant impairment (APA, 2000).

Other Symptoms

Other disorders can cooccur with PTSD, ASD, or adjustment disorder. One of the most commonly cooccurring disorders is depression. In a national survey of more than 5,000 individuals, nearly half of individuals meeting criteria for PTSD also met criteria for depression (Kessler et al., 1995). PTSD has also been associated with higher rates of substance use, especially among war veterans (Kulka et al., 1990). In addition, PTSD has been associated with other anxiety disorders, such as panic disorder, social phobia, and generalized anxiety disorder (Kessler et al., 1995).

In addition to other diagnoses, there are a number of responses that are often associated with PTSD. For example, individuals with PTSD often experience dissociative symptoms during or after the traumatic event (Griffin, Resick, & Mechanic, 1997; van der Kolk & Fisler, 1995). Deficits in memory specific to the trauma, as well as deficits in short-term memory in general, have also been noted (Bremner et al., 1993; Briere & Conte, 1993). Not only psychological reactions, but also sustained physiological reactions have been well documented (Friedman, 2001; Yehuda, Giller, Levengood, Southwick, & Siever, 1995).

Risk Factors

It is important to note that not all individuals who experience a traumatic event develop a psychological disorder. For example, in a prospective study of rape victims, 94% of the participants endorsed enough symptoms to be diagnosed with PTSD one week after the rape (Rothbaum, Foa, Riggs, Murdock, & Walsh, 1992). However, when assessed 3 months after the rape, only 47% met PTSD criteria (Rothbaum et al., 1992). These statistics suggest that most rape victims experience intense PTSD symptoms immediately following the rape. Over half of the victims naturally recover from these symptoms over time. The others, however, remain symptomatic.

Researchers have begun to identify risk factors for developing a psychological disorder after exposure to trauma. Gender seems to be one such factor; research suggests that more women than men develop PTSD (Brewin, Andrews, & Valentine, 2000; Kessler et al., 1995). Individuals lacking social support are also at greater risk for developing a psychological disorder (Brewin et al., 2000). In addition, those who dissociate during a trauma are more likely to have lingering psychopathology (O'Toole, Marshall, Schureck & Dobson, 1999). There are also some characteristics of the trauma itself that increase the likelihood of developing PTSD. For example, it seems that interpersonal traumas, such as war or sexual assault, more often result in PTSD than do natural traumas, such as an earthquake or fire (Kessler et al., 1995).

TRICHOTILLOMANIA

Trichotillomania is a disorder that involves the repeated pulling of one's hair, resulting in noticeable hair loss. Individuals with trichotillomania experience internal sensations of anxiety or tension that immediately precede pulling (and/or an attempt to resist pulling) and subside only after pulling. Cosmetic complaints resulting from hair loss are a primary concern for persons with trichotillomania, but complications in social, occupational, psychological, and medical functioning are also common. Although hair pulling is rarely performed in public, hair loss often results in negative social interactions and the avoidance of many social and occupational settings. In addition to these social and occupational disturbances, a variety of physical and psychological sequelae can accompany trichotillomania. Gastrointestinal problems resulting from trichobezoars (hairballs) associated with trichophagia (eating of hair), dermatological problems, and comorbid psychological problems such as obsessive-compulsive disorder (OCD), mood disorders, and anxiety disorders can cooccur. Although hair pulling resembles a compulsion, trichotillomania appears to be more of a problem with impulse control and is therefore classified as an impulse control disorder.

Demographics

The prevalence of trichotillomania is unclear, but it has been estimated that 0.5% to 2% of college students meet or have previously met diagnostic criteria for trichotillomania. A considerably higher percentage of individuals engage in hair pulling at subdiagnostic levels. Little epidemiological data exist for children or older adults. Adults with trichotillomania are more likely to be female than male, but this gender difference appears to be less exaggerated in children.

Course and Patterns

Trichotillomania can begin at any age but typically starts in adolescence and is often preceded by a significant life event or problem. Hair pulling occurs most frequently from the scalp, eyebrows, and eyelashes, but can involve any body region with hair (e.g., pubic region, arms, legs). Hair pulling typically involves the pulling of only one hair at a time. Prior to the actual removal of a hair, individuals with trichotillomania often engage in a variety of prepulling behaviors including touching, stroking, and manipulating hairs and/or wrapping the hair around a finger. Although hairs are most commonly pulled with the fingers, some individuals pull hairs with cosmetic utensils such as a tweezers. After the hair is removed, individuals engage in a variety of postpulling behaviors including discarding, manipulating, sucking, chewing, or biting the hair. In addition, some individuals engage in trichophagia.

There are two types of hair pulling: automatic and focused. Automatic hairpulling occurs outside of the individual's awareness. Because individuals are unaware of their pulling, they frequently catch themselves pulling, often after removing a considerable number of hairs. Automatic pulling most commonly occurs when an individual is engaged in an activity that requires a high degree of concentration. Focused pulling, in contrast, involves pulling in which the individual is fully aware of the act. Individuals who engage in this type of hair pulling often seek specific situations or settings in which to pull (e.g., the bathroom). Individuals who engage in focused pulling often report an overwhelming urge or need to pull and report that pulling satisfies this urge by making it less intense or making it go away. In addition, individuals who engage in focused pulling report that attempts to suppress pulling makes the urge more intense. Typically, persons with trichotillomania engage in both automatic and focused pulling.

Etiology

Although the cause of trichotillomania is unknown, some experts contend that trichotillomania has genetic or neurobiological underpinnings. Two neurotransmitter systems, serotonin and dopamine, are thought to play a role in trichotillomania. In addition, it has been hypothesized that individuals who pull hair have an increased tolerance for pain, possibly due to abnormalities in the opiate system (a neurochemical involved in the regulation of pain sensation).

From a behavioral perspective, hair pulling appears to remove or reduce the anxiety or tension that precedes it, thus making individuals more likely to pull in the future (i.e., negative reinforcement). It is also hypothesized that, for some individuals with trichotillomania, hair pulling is positively reinforced by stimulation to the site of pulling or to the fingers (positive reinforcement).

Assessment and Treatment

Hair pulling associated with trichotillomania is typically evaluated and monitored through indirect measures such as interviews and questionnaires. Two commonly used questionnaires are the Massachusetts General Hospital Hairpulling Scale and the National Institute of Mental Health Trichotillomania Scales. When direct measures are used, they usually include event recording (recording each time a hair is pulled), hair collection, and photographs of affected areas (collected across several days to monitor and rate the regrowth of hair).

The most common treatments for trichotillomania are pharmacotherapy and behavior therapy. Because hair pulling often resembles the compulsive behavior found in OCD, some of the first drugs used to treat trichotillomania were those used for treating compulsions. Serotonin reuptake inhibiters (SSRIs), a form of antidepressants affecting levels of serotonin, were among the first used and continue to be one of the most commonly prescribed medications.

Common SSRIs for trichotillomania include clomipramine and fluoxetine. Additionally, some individuals respond well to a combination of SSRIs and neuroleptics, which affect levels of dopamine. The most common neuroleptics used in combination with SSRIs are pimozide and risperidone. Several other pharmacological treatments have been used with varying degrees of success (e.g., tricyclic antidepressants, monoamine oxidase inhibitors, opiate antagonists).

The most effective behavioral treatment for trichotillomania is habit reversal, a multielement treatment shown to be effective for treating a variety of repetitive behaviors. The components of habit reversal include awareness, competing response, and social support training. With the help of a trained therapist, an individual first becomes more aware of pulling by learning to recognize high-risk situations (who, what, where), thoughts, and feelings (e.g., urges) that indicate that he or she is about to pull. After awareness is obtained, the individual learns to engage in a response that is incompatible with hair pulling (e.g., fist clenching) before the pulling occurs. Social support is used to prompt the individual to use this competing response and to provide encouragement throughout the treatment process.

TRICYCLIC ANTIDEPRESSANTS

The tricyclic antidepressants were first introduced in the early 1960s and soon became widely used for the treatment of depression. The introduction of the tricyclics, along with the development of the phenothiazine antipsychotics for the treatment of Schizophrenia and the use of lithium for treatment of bipolar illness, ushered in the modern era of psychopharmacology. The robust effectiveness of the tricyclics is somewhat offset by their problematic side effects, and although in recent years they have been largely supplanted by the selective serotonin reuptake inhibitors (SSRIs) as first line treatment, the tricyclics still remain a widely used treatment for depression and other psychiatric and neurologic syndromes.

Clinical Pharmacology

The tricyclic antidepressants are so named because all of the compounds share a three-ring substructure and differ primarily in the side chain attached to the middle ring (see Figure 1). The most frequently prescribed are imipramine, amitriptyline, desipramine, and nortriptyline. (Note that desipramine and nortriptyline are simply the demethylated metabolites of imipramine and amitriptyline, respectively.)

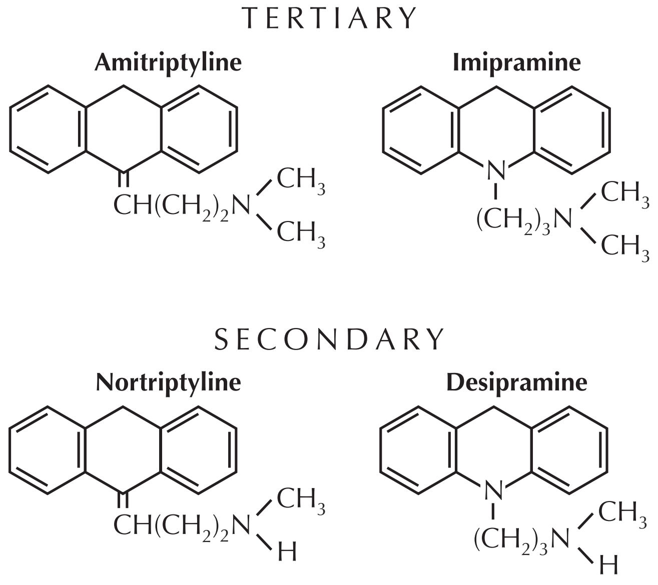

Figure 1. Tricyclic antidepressants compounds.

The tricyclics are lipid soluble and are given orally; they are well absorbed from the gastrointestinal tract. There is considerable first-pass effect in the liver, where the drugs are metabolized by transformation of the tricyclic nucleus and alterations of the side chain. The critical step in metabolism is hydroxylation at the 2 position of the ring, thereby creating a water-soluble metabolite that is then secreted from the body.

A critical advance in maximizing the effectiveness of tricyclics has been the documentation of a strong correlation between plasma level of antidepressant and clinical outcome (Glassman et al., 1985). In patients treated with desipramine and imipramine, there is a threshold effect such that maximum response is achieved at plasma levels over 150 ng per ml and 200 ngs per ml, respectively. Patients treated with nortriptyline have a curvilinear response, or therapeutic window, in which maximum response is achieved when the plasma level is in the range between 50 and 150 ng per ml (see Figure 2).

Mechanism of Action

The major effect of the tricyclic antidepressants is to block the reuptake of monoamine neurotransmitters. The secondary amine tricyclics, desipramine and nortriptyline, block the reuptake of norepinephrine more specifically, whereas the tertiary amine tricyclics, imipramine and amytriptyline, to some degree block the reuptake of both norepinephrine and serotonin. Competitive blockade of the serotonin and norepinephrine uptake pumps is believed to potentiate monoaminergic neurotransmission. However,

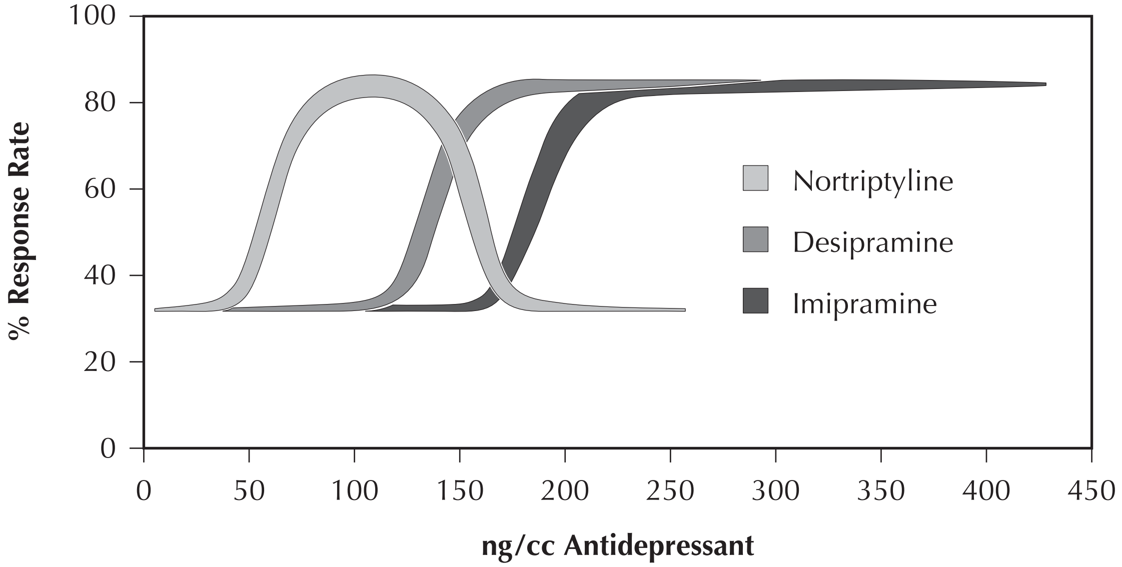

Figure 2. The relationship between blood levels and outcome: Comparison of three antidepressants.

even though blockade of amine uptake occurs within 12 hours, the antidepressant effects of the tricyclics do not occur for several weeks. Recent studies have focused on second messenger systems as critical mediators between receptor activity and gene transcription; this process may explain both antidepressant activity and delay of onset of action (Nestler, Terwilliger, & Duman, 1989).

Side Effects

Despite their robust effectiveness, the clinical use of tricyclic antidepressants has been limited by their side effects. The problems range from minimal seriousness with high nuisance value that can markedly reduce patient compliance, to problems of potential lethality in certain patient populations. The most frequent side effects of tricyclics are due to their peripheral anticholinergic (antimuscarinic) effects, which account for dry mouth, constipation, tachycardia, and blurred vision (Richelson, 1989). In older patients, the anticholinergic effect can result in urinary retention and acute confusional states. The tricyclics also block histamine receptors, which may be related to the significant weight gain that is associated with long-term treatment in some patients.

Another frequent and significant side effect of the tricyclic antidepressants is orthostatic hypotension (Richelson, 1989). This effect results in part from peripheral alpha-adrenergic receptor blockade and occurs in approximately 10% of patients treated with tricyclics. Orthostatic hypotension can result in serious injury and fatalities.

The cardiovascular effects of the tricyclics account for most of the morbidity and mortality associated with these medications (Roose & Glassman, 1989). The tricyclics are Type 1A antiarrhythmic drugs and have a quinidine-like action on the heart that results in an antiarrhythmic effect and slowing of cardiac conduction. Consequently, tricyclics can be dangerous in patients with preexisting conduction system disease such as bundle branch block and can increase mortality in patients with ischemic heart disease. When taken in overdose, tricyclics are frequently lethal due to heart block and ventricular tachycardia. The extensive cardiovascular effects of the tricyclic antidepressants serve as a reminder that the therapeutic label of a medication (an antidepressant) does not necessarily describe all of the systems that are significantly affected. The clinician must be equally aware of the effects of a medication other than the intended mechanism of action.

Clinical Indications

The tricyclic antidepressants are effective in the treatment of unipolar major depressive disorder (Richelson, 1989). They are also effective in the treatment of a bipolar depressive episode. However, because their use can cause a switch into mania, it is standard practice for a depressed bipolar patient to be treated with both a mood stabilizer and an antidepressant. Studies have also established the effectiveness of the tricyclics in the treatment of dysthymia, a form of chronic mild depression that often presents early in life (Kocsis, 1997).

Despite being labeled antidepressants, the tricyclics also produce significant benefit in the treatment of certain anxiety disorders, notably panic attacks and generalized anxiety (Roy-Byrne & Lydiard, 1989). Tricyclics have been shown to decrease significantly the rate of binges in patients with bulimia, although they have been ineffective in the treatment of anorexia nervosa (Walsh et al., 1997). Tricyclics are also used for the treatment of other conditions

that are not considered primarily psychiatric but that often are accompanied by affective or anxiety symptoms. Notable among these conditions are irritable bowel syndrome, migraine headaches, and chronic pain.

Although the tricyclic antidepressants have been largely supplanted by the SSRIs as the first-line treatment for depressive or anxiety disorders, they remain widely used compounds. Up to 40% of depressed patients do not achieve remission when treated with an SSRI alone, and it is common clinical practice to combine an SSRI with a tricyclic as a second treatment strategy. Furthermore, some types of depressive disorders may preferentially respond to the tricyclics compared to the SSRIs (e.g., the melancholic subtype of depression). In addition, age may affect response to antidepressant medication, and in the geriatric patient, tricyclics may be more effective than SSRIs (Roose & Suthers, 1998). A recent study showed that nortriptyline in combination with monthly interpersonal psychotherapy is an effective treatment to prevent recurrence of depression in the geriatric population (Reynolds et al., 1999). Unfortunately, the nuisance and potentially dangerous side effects of tricyclics are greatest in the older population. All of the tricyclics are available as generic compounds and so are significantly less expensive than most other antidepressants. In summary, the tricyclics remain in widespread clinic use, but their problematic side-effect profile means that they are rarely used as a first-line treatment for depression.

TRUST

Trust is "the expectancy of positive (or nonnegative) outcomes that one can receive based on the expected action of another party in an interaction characterized by uncertainty" (Bhattacharya, Devinney, & Pillutla, 1998, p. 462). Trust is both a dispositional (personality) variable and a temporary state.

Trust as a Dispositional Variable

Those who are trusting tend to give others the benefit of the doubt unless they have clear evidence that someone is untrustworthy. In social dilemma situations, they expect others to cooperate (Komorita & Parks, 1994), and they avoid using deception (Rotter, 1980). Trust is negatively related to Machiavellianism and authoritarianism (Deutsch, 1960; Gurtman, 1992).

Those who distrust sometimes make sinister attribution errors, explaining another's negative actions in terms of hostile interpersonal motives (Kramer, 1994). Distrust and trust are usually considered opposite poles on one continuum even though they may be qualitatively different (Lewicki, McAllister, & Bies, 1998).

Trust as a Temporary State

Research investigating trust as a temporary state often explores one of three themes:

1. *Trust and cooperative motivational orientation.* In this theme, trust is a cognitive and emotional state related to cooperative motivational orientation (MO). Thus, in some situations (e.g., prisoner's dilemma experiments) cooperative behavior reflects trust (Kee, 1969; McAllister, 1995).

2. *Trust and predictability.* This theme suggests that a person who behaves consistently is trustworthy (e.g., Butler, 1991). Predictability allows others to anticipate whether a person will keep his or her word—called knowledge-based trust (Shapiro, Sheppard, & Cheraskin, 1992). Even if a person is not cooperative, if he or she is consistent, then others can devise strategies for dealing with that person. Finally, a pattern of repeated, cooperative behavior can establish trust (Kramer, 1999; Lindskold, 1978).
3. *Trust and a problem-solving perspective.* This theme relates trust to a problem-solving orientation in bargaining. Kimmel, Pruitt, Magenau, Konar-Goldband, and Carnevale (1980) observed that trust increases information sharing and problem-solving efforts, yet it has little effect on negotiated payoffs (also see Kee, 1969). This paradox may occur because trust improves the quality of the parties' relationship rather than increases their ability to resolve specific issues. Indeed, friends are often less likely than strangers to discover integrative bargaining solutions because maintaining the trusting relationship is more important than are short-term payoffs (Halpern, 1994).

   Shapiro et al. (1992) suggested that trust is maximized when the cooperative MO perspective and the problem-solving perspective merge into what they call identification-based trust. Here, each side internalizes the other's interests, developing shared interests.

Antecedents of Trust

Numerous social factors such as benevolence can create trust (Kramer, 1999; Mayer, Davis, & Schoorman, 1995). Mental shortcuts called cognitive heuristics also facilitate trust or distrust—sometimes erroneously. For example, people selectively notice, recall, and evaluate certain information (e.g., vivid evidence of betrayal) when deciding whether to trust another (Ross & LaCroix, 1996).

Consequences of Trust

There are numerous consequences of trust, including a willingness to be vulnerable to another (Pruitt, 1981). Trust may also enhance relationships, causing greater empathy and mutual concern (Lewicki, Saunders, & Minton, 1999).

However, trust can prove unwise (Wicks, Berman, & Jones, 1999). The trusting party is unlikely to recognize evidence of betrayal. Trust may also lead to using fewer objective standards and verification mechanisms to ensure compliance (Ross & LaCroix, 1996). Thus, trust may sometimes cause someone to be blind to another person's untrustworthy behavior.

In conclusion, psychologists see trust as both a dispositional trait and a temporary state. Within the latter perspective, research themes have emerged investigating trust and cooperative MO, predictability, and problem solving. Trust is a social, affective, and cognitive phenomenon with numerous antecedents; if correctly placed, trust may yield lasting benefits to the involved parties.

TWELVE-STEP PROGRAMS

In 1935 Bill Wilson, a stockbroker, and Bob Smith, a physician, met for the first time in Akron, Ohio. Both men were struggling with the disease of alcoholism. Bob did not want another person preaching to him about staying sober, but he agreed to see Bill for a few minutes. The two men talked about their common problem and shared their experiences. Bill explained that he was not there to keep Bob sober; he was there to keep himself sober. He had a spiritual awakening during his last detoxification, but it was not enough to keep him sober. He had just lost a business deal, and he was thinking about drinking to ease the pain. Medical science had no answer for the chronic alcoholic at the time. The men talked for hours, and they struck a bond. They found that if they talked about their common problems, they could overcome the compulsion to drink. From this first meeting, Alcoholics Anonymous (AA) was born. AA is a fellowship of men and women who share their strength and hope with each other that they may solve their common problem with alcoholism. The Big Book of Alcoholics Anonymous, first published in 1939, listed the twelve steps that are suggested as a program of recovery. Many other groups have used the twelve steps to develop similar programs of recovery, including Narcotics Anonymous, Cocaine Anonymous, Overeaters Anonymous, Emotions Anonymous, Gamblers Anonymous, and Sexaholics Anonymous.

Twelve-step programs revolve around regular attendance at group meetings, sponsorship with another more experienced member, and a spiritual journey to a higher power. Alcohol and drug treatment facilities using the twelve steps as the foundation of treatment began with Hazelden in 1949 and have spread around the world.

The Twelve Steps

1. We admitted we were powerless over alcohol—that our lives had become unmanageable.
2. We came to believe that a Power greater than ourselves could restore us to sanity.
3. We made a decision to turn our will and our lives over to the care of God *as we understood Him.*
4. We made a searching and fearless moral inventory of ourselves.
5. We admitted to God, ourselves and another human being the exact nature of our wrongs.
6. We were entirely ready to have God remove all these defects of character.
7. We humbly asked Him to remove our shortcomings.
8. We made a list of all persons we had harmed, and became willing to make amends to them all.
9. We made direct amends to such people wherever possible, except when to do so would injure them or others.
10. We continued to take personal inventory and when we were wrong, promptly admitted it.
11. We sought through prayer and meditation to improve our conscious contact with God as we understood Him, praying only for the knowledge of His will for us and the power to carry that out.
12. Having had a spiritual awakening as the result of these steps, we tried to carry this message to alcoholics and to practice these principles in all our affairs. (Alcoholics Anonymous, 1976)

Either a counselor or a sponsor walks recovering persons through the twelve steps. First, recovering persons need to admit how powerless their life is over the addictive substance or behavior. This is accomplished by sharing recurrent psychological, social, or physical problems caused by or exacerbated by the addiction. Recovering individuals need to see that whatever they tried to do to bring their illness under control failed. They might have been able to stay clean for a short period of time, but they always returned to the addiction. Then they are encouraged to come to believe that a Power greater than themselves can restore them to sanity. At first that might be the recovery group, but soon they come to think about God. In Step 3 the individuals make a decision to turn their life and will over to the care of God as they understand Him. This is a spiritual program, not a religious one, so the addicts are allowed great leeway in choosing the higher power of their own understanding. Then addicts are encouraged to clean house by taking a personal inventory. This is a thorough autobiography including their life story and all assets and liabilities. In Step 5 recovering persons verbalize to themselves, god, and another human being the exact nature of their wrongs. This eases the guilt of the past and prepares for a new life in recovery. In Step 6 addicts become ready to give all defects of character over to the care of God. Then in Step 7 they ask God to remove all of these shortcomings. Step 8 involves making a list of everyone harmed by the addiction, and Step 9 encourages the addict to make direct amends whenever possible without hurting anyone. In Step 10 addicts take a daily personal inventory encouraging themselves when they succeed and correcting old behavior when necessary. Step 11 is where they seek conscious contact with god through prayer and meditation and ask God for specific direction. In Step 12 addicts continue to monitor

themselves and carry the recovery message to persons still suffering.

TWO-PROCESS LEARNING THEORY

The central premise of two-process learning theory is that the laws of classical and instrumental conditioning are not functionally equivalent. During the first half of the twentieth century, the general trend was to treat classical and instrumental conditioning as obeying the same laws (Guthrie, 1935; Hull, 1929, 1943). Nevertheless, even during its formative period, learning theory had expressed an alternative view. As early as 1928, Miler and Konorski had distinguished between two forms of conditioned response: Type I was Pavlov's secretory conditioned response (CR), formed by establishing a positive correlation between the conditioned stimulus (CS) and the unconditioned stimulus (US); Type II differed from the classical CR in that its occurrence was dependent on its consequences. Despite the early work of Konorski and others (Hilgard, 1937; Schlosberg, 1937; Skinner, 1938) regarding the adequacy of uniprocess theories of learning, it was not until drive reduction theory encountered theoretical problems accounting for avoidance learning that two-process theory emerged to challenge the prevailing view. In drive reduction theory, the motive for the avoidance response derived from the occurrence of an aversive US and the reinforcement of the response from US termination. However, because the avoidance response prevents the US from occurring, the theory cannot account for the learning or maintenance of avoidance behavior (Kimble, 1961).

To resolve this problem, Mowrer (1947, 1950) proposed that avoidance learning was the result of two processes. Fear-instigated avoidance behavior and the reduction of fear following the avoidance response maintained the behavior. Classical conditioning established the fear reaction to the CS by pairing the CS with an aversive US. This view contrasted sharply with Hull's (1929) account. Hull had argued that the cessation of an aversive US was reinforcing. By demonstrating that there was no difference in the conditioning of fear when the onset of the aversive US coincided with the CS or when the CS was coincident with both the onset and the offset of the aversive event, Mowrer showed that fear was formed through classical conditioning. In this case, classical conditioning established the association between the CS and the fear CR. Once aroused, fear motivated instrumental behavior. Reducing the fear reinforced the response that was successful in removing the CS. Cast in this form, two-process theory assigned considerable importance to classical conditioning; the processes established by this form of learning functioned as motivators or reinforcers mediating instrumental behavior.

Ironically, Hull (1929, 1931) provided the hypothetical mechanism that served as the basis for extending two-process theory to appetitive behavior. For Hull, components of the consummatory response became anticipatory following repeated presentations of the US. These fractional anticipatory goal reactions (r_g) were associated with stimuli that antedate (and hence signal) the appetitive US. The r_g mechanism also produced sensory aftereffects, which were symbolized as s_g. Although Hull used $r_g - s_g$ as an associative mechanism to explain disrupted behavior following a change in the quality of a reward, later theorists employed it as a device that mediated incentive motivation: $r_g - s_g$ somehow selectively energized responses that had previously been successful in enabling the animal to encounter a goal object (Logan, 1960; Seward, 1952; Spence, 1956).

Because fear and $r_g - s_g$ were treated as implicit peripheral CRs, considerable research was devoted to determining their role in mediating instrumental behavior. Classically conditioned responses such as heart rate and salivation were used to index these implicit events and the temporal relationship between them and instrumental responses. After an exhaustive review of the literature, Rescorla and Solomon (1967) concluded that the strategy of indexing these inferred events by overt CRs and mapping their relationship to instrumental activity failed because there was no temporal consistency between the observable Pavlovian CRs and the sequence of instrumental responses. In the course of an experiment, the CR might precede, occur coincident with, or follow the instrumental response (Sheffield, 1965).

Rescorla and Solomon (1967) argued that a more promising approach was to view the events established by classical conditioning as central states and to determine their role indirectly using a transfer-of-control paradigm. The transfer-of-control procedure involves multiple stages of training. Classical or instrumental conditioning is given during the first stage of learning; then, depending on which of the two conditioning procedures was first administered, subjects receive the other conditioning procedure. In the third or test phase, while the animal is engaged in instrumental activity, the Pavlovian CS is administered. Facilitation or disruption of the instrumental response following the presentation of the CS is taken as evidence that the CS has evoked a central state (Mellgren & Ost, 1969; Shapiro & Miller, 1965).

Trapold and Overmier (1972) questioned the notion that classical and instrumental training establishes distinct Pavlovian and instrumental processes. They suggested in-

stead the adoption of a more neutral terminology, namely, response-independent and response-dependent learning. One implication of this usage is a greater reciprocity between the two forms of learning: Response-independent learning is not necessarily a result of classical conditioning, even though the process established by this type of learning may affect instrumental behavior. Moreover, the representation formed during response-dependent learning may interact with stimulus-stimulus associations (Alloy & Ehrman, 1981).

The initial formulation of two-process theory held that the laws governing the formation of associations were different although what was learned (viz., stimulus-response associations) were the same. By contrast, the current view argues that classical and instrumental conditioning obeys the same laws. They differ, however, in the sort of associations established by the two training procedures. Classical conditioning promotes the formation of stimulus-stimulus (S-S) associations, whereas instrumental conditioning results in the establishment of response-stimulus (R-S) associations (e.g., Dickinson, 1980; Mackintosh, 1974). One problem with this analysis is that some forms of classical conditioning (e.g., second-order conditioning) seemingly form S-R associations (Rescorla, 1974). Logan (1988) proposed a possible resolution of this dilemma. He argues that the second-order stimulus (CS_2) establishes two mediating links to the CR. One involves an association between CS_2 and representations of consequent events such as the first-order CS (CS_1) or the US; a second mediating link is response-produced stimulation generated from the CR. The salience of these associative connections determines which one controls the CR. Presumably, the sensory properties of the US are more salient than the stimulation produced by the UR in first-order conditioning; but with second-order conditioning, CR-produced feedback is more salient than sensory qualities of CS_1.

A second problem concerns the nature of response selection in instrumental conditioning. Whereas S-S associations can explain the initiation of behavior by assuming that the CS evokes a representation of the US, which in turn elicits the CR, R-S learning must rely on the formation of two separate representations: one between the context and the US, and the other between the US and the response. The excitation necessary for response evocation must flow from the US to the response. This conceptualization does not enjoy a substantial empirical base (Mackintosh, 1983).

Dickinson's (1989) expectancy theory of conditioning provides a possible resolution to this conundrum. The theory retains a mechanistic associationistic explanation for classical conditioning but advances an intentional, cognitive account for nonautomatic forms of instrumental behavior. The mechanistic account suffices for response elicitation in classical conditioning and assigns a role for Pavlovian processes in mediating some types of instrumental learning that evidence automaticity, but voluntary behavior involves the activation of expectancies. Thus, when an animal experiences a contingency between its behavior and some outcome, an expectancy embodying the content of the contingency is formed. The association formed by the contingency is mapped into a declarative structure that represents the actual state of affairs. The content of the representation is of the form "this action leads to that reinforcer." If the content of this belief is accompanied by a relevant motivational state that serves to enhance the desirability of the reinforcer, then the activated expectancy results in the issuance of a command to execute the response. Thus, knowledge and desire form the basis of voluntary behavior through some sort of computational process. The nature of the psychological mechanism (if, indeed, there is one) that captures the intentionality of instrumental conditioning remains, as Dickinson himself pointed out, open.

U

UNCONSCIOUS

The unconscious is a hypothetical construct used to describe behaviors, phenomena, material, processes, and so on that are out of immediate awareness (English & English, 1958/1974). Prior to Freud, this concept was used to explain a variety of behavior, such as dissociation, mesmerism, and trancework. Freud initiated the formal term *unconscious* (Rychlack, 1981). Later, Erickson and Rossi refined it via Ericksonian hypnotherapy and state-dependent memory learning and behavior systems or the mind-body approaches (Erickson, Rossi, & Rossi, 1976; Rossi, 1993).

Definitions of the unconscious vary depending on one's theoretical perspective. English and English (1958/1974) found 39 distinct meanings.

Historical Views

Psychoanalysis

Sigmund Freud was the first modern-day theorist to explore personality in depth. He divided awareness into three levels: (1) conscious awareness, (2) preconscious awareness, and (3) unconscious awareness. Conscious awareness includes any materials, experiences, learnings, perceptions, feelings, or thoughts in immediate awareness. The preconscious—an intermediate level—consists of any materials that enter conscious awareness. The unconscious comprises all repressed thoughts, feelings, behaviors, memories, experiences, learnings, defense mechanisms, sexual impulses, instincts, id impulses, wishes, dreams, psychological conflicts, and so on and remains outside awareness (Hall & Lindsey, 1978; Norby & Hall, 1974).

Hypnotic, Ericksonian Views

Erickson worked with various processes of the unconscious (Erickson et al., 1976; Havens, 1985). His view of the unconscious, developed through trancework, consisted of a reservoir of past memories, or a storehouse of learning patterned from experiences (Beahrs, 1971; McGarty, 1985; Yapko, 1986). The unconscious is considered to be a positive constructive process. The work of Erickson connected the trance state to unconscious functioning (Yapko, 1984).

Trance provides access to the unconscious process. Specific trance (or subconscious) behaviors include age regression (remembering past memories without prior conscious recollections); age progression (experiencing futuristic scenarios before the actual events occur); hidden observer phenomena (imagining watching oneself doing something); dissociation; catalepsy (muscular suspension or immobility and rigidity in the limbs, based on concentration/suggestion); ideodynamic or psychomotor behaviors (involuntary behavioral movements—finger movements, hand movements, etc.—outside ordinary conscious awareness); autohypnosis; anesthesia (by suggestions and concentration); amnesia; automatic writing; imagery; time distortion; eye closure; and relaxation (Carich, 1990a; Erickson et al. 1976). Lankton and Lankton (1983) furthered the Ericksonian view of the unconscious by emphasizing a right-hemispheric physiological base along with behaviors and processes such as spatial modes, pantomine (nonverbal movement), involuntary movements, imagery, sensory modalities, intuition, artistic-creative tendencies, literalism, psychophysiological functioning, music, symbolic representations/meanings, rhythmic patterning, and spontaneity.

Rossi (1993) took a psychophysiological view of the unconscious along with the previously stated Ericksonian views. He postulated that the key to the unconscious processes and the issue of causality is the state-dependent memory learning and behavior (SDML&B) system. Rossi (1987) explained state-dependent memory as "what is learned and remembered is dependent upon one's psychophysiological state at the time of the experience" (p. 372).

The SDML&B system is considered to stem from the limbic-hypothalamic system, which regulates much of human behavior and brain activity through information substances or messenger molecules. These regulatory processes are the substance of the unconscious. Rossi (1993) further contended that behaviors and/or learning consist of encoding perceptions into state-dependent memories at the limbic-hypothalamic level. More specifically, learning, memories, and perceptions are transduced into information via molecular processes within the brain, whereas sensory input is transduced through cellular interaction. This, then, is primarily the basis of the unconscious processes. Rossi (1993) also related this with psychophysiological rhythms (circadian and ultradian cycles). Ultradian cycles are the natural rest cycles that facilitate rest states (Rossi

& Nimmons, 1991) and provide a window into the unconscious. The conceptual meaning of the unconscious is controversial. Research into the unconscious and the related concepts of hypnosis and dissociation is continuing. Kihlstrom (1987) cited research suggesting that humans cognitively process information that is not in immediate awareness. Epstein (1994, p. 710) explained that "the cognitive unconscious is a fundamentally adaptive system that automatically, effortlessly, and intuitively organizes experience and directs behavior. . . . Most information processing occurs automatically and effortlessly outside of awareness."

Consciousness is best viewed on a continuum, ranging in degrees, or levels, from the storage of information and the processing of that information in immediate awareness to a lack of awareness (unconsciousness).

Applications

Among the applications of the unconscious are changing behaviors and resolving problems. To accomplish these goals, the unconscious must be accessed and used. People are generally self-programmed through a series of choices based on a variety of experiences. Many problems are self-programmed at unconscious levels (unconscious choices or choices made at unconscious levels) and need to be reprogrammed at unconscious levels. Some methods of accessing and using the unconscious are internal visualization or imagery, fantasy and daydreams, dreams, self-talk, music, art, body rhythms (basic rest activity cycles), relaxation, and hypnotic techniques.

Imagery is the internal visualization of some image or scenario with a theme (Aroaz, 1982, 1985). By using imagery, fantasy, and daydreams, one gains the experience that something actually happened. When using imagery, one should use sensory modes (auditory [hearing], kinesthetic [movement], taste, and smell; Aroaz, 1982, 1985). To prepare for upcoming events, one should develop a detailed image or scenario of the event and reactively rehearse the scenario, imagining successfully completing the task.

Aroaz (1982, 1985) suggested that self-talk is a type of hypnotic suggestion that self-programs one's mind at an unconscious or subconscious level. By monitoring one's self-statements and changing them, one can reprogram one's unconscious belief systems.

Other ways to access unconscious processes and change dysfunctional behavior are through hypnosis and relaxation techniques that can directly access unconscious processes. For more information on hypnotic techniques, see Hammond (1990) and Carich (1990a, 1990b).

Rossi (1987, 1993) emphasized the importance of the body's naturalistic rhythms (ultradian rest cycles). The unconscious can be accessed by taking advantage of rest cycles (Rossi & Nimmons, 1991).

Both music and art can serve as pathways to the unconscious if one has learned to be receptive. Literally, most music and artwork involve unconscious elements (Lankton & Lankton, 1983).

UNIVERSAL HEALTH CARE

Universal health care, also known as national health insurance (NHI), is defined as health care for all residents of the United States funded by the federal government under its single-payer system. There are many examples of universal health care throughout the world (e.g., the United Kingdom, Sweden, Canada), and, in fact, the United States remains the only industrialized nation without government-sponsored single-payer health care.

NHI would constitute a wide-scale, comprehensive redistribution of health care services. Because there would be no aspect of the health care sector that would not be significantly affected, its potential implementation galvanizes every stakeholder to adopt a strong pro or con position. The American Medical Association (AMA) opposes it because it would further erode its already weakened—and once virtually monopoly—status. The private health insurance industry that in the decade of the 1990s burgeoned into various versions of managed care opposes it because it wants no increase in a federal health bureaucracy that would impede its growth. The welfare sector favors it because it would bring health care to every resident and would guarantee the continuation of a welfare system that recently has been subjected to severe cutbacks.

Widespread interest in universal health care began in the 1930s. During this era of the Great Depression, not only was there high unemployment, but also there was no private health insurance. The AMA successfully campaigned against government-sponsored health care, calling it socialized medicine, and instead favored the expansion of county medical clinics to meet the needs of the unemployed. During this same period the Blue Cross/Blue Shield plans were created as the first of a long series of private-sector solutions to the need for extended health care coverage.

During World War II a far-reaching private-sector alternative to government sponsored health care inadvertently emerged. The nation had to relocate millions of Americans to work in the defense industry. Wages were frozen by law, so increased compensation could not be used to lure potential workers from the rural areas. The government permitted health coverage in lieu of money, and because millions of Americans could not afford to pay the doctor, the incentive was successful. The labor unions liked the security it accorded their members, and they made employer-sponsored health care a permanent issue at the collective bargaining table. Thus, with almost all employed persons having health care paid by their employers, the private sector had achieved nearly universal health coverage, at least for those with jobs.

This phenomenon prompted the proponents of government-sponsored universal health care to change their strategy. Because most of the labor force seemed satisfied with employer-sponsored health insurance, they directed their attention to the millions of unemployed, disabled, and elderly Americans. Seemingly overnight, Titles 18 and 19 were added to the Social Security Act, and thus in the mid-1960s Medicare and Medicaid were born. These programs expanded through the years, and by 2000 it could be said that the federal government covered the health care of 50% of Americans. There was no universal government plan, but the combination of all federal health programs (Medicare, Medicaid, Veterans Administration, CHAMPUS, Federal Employees Benefits Program, Indian Affairs, etc.) made the United States government by the year 2000 the largest single payer of health care in the world.

Shortly after the enactment of Medicare and Medicaid, strong interest in universal health care again emerged, championed by Senator Edward (Ted) Kennedy, who had become the chair of the U.S. Senate Subcommittee on Health. Referring in the early 1970s to what he called the "patchwork quilt" of inefficient, duplicative health care in America, he initiated hearings toward the objective of a government-sponsored universal system. NHI seemed imminent when the pendulum abruptly swung the other way. Senator Russell Long, also a Democrat and chair of the overarching Senate Finance Committee, replaced Senator Kennedy with Senator Herman Talmage. The Congress went in the opposite direction and enacted in 1974 the bipartisan HMO Enabling Act. This funded new health maintenance organizations and laid the groundwork for the managed health care era of the 1980s and 1990s, a far-reaching alternative that saw a near-universal system through the industrialization of the private sector.

The Jackson Hole Group, composed of a number of prominent health economists, saw managed competition as the solution to the spiraling costs of health care. They envisaged a system in which an employer provided each employee with a list of approved plans, as many as 20, with various degrees of coverage and copayments, and with some plans requiring the employee to supplement the employer's basic payment. The employee was empowered with knowledge of quality and extensiveness and had an annual choice from among competing plans. The managed care plans that emerged in the 1980s were only partial implementations of this concept, lacking full disclosure and employee choice, but they filled an economic gap. By 2000 there were 175 million Americans who were covered under some form of managed health care. This burgeoning growth was fueled in part by the enactment of Diagnosis Related Groups (DRGs) in 1983, a system in which hospitals are paid for the number of days allotted for each of over 300 diagnostic categories. Because failure to meet the allotments meant that a hospital would lose money, companies designed toward efficiency of care suddenly appeared and prospered.

A serious effort to expand into government-sponsored universal health care was mounted by the Clinton administration. Hillary Rodham Clinton chaired an ill-fated task force in 1993 and 1994 that attempted to meld the concept of managed competition with a federal single-payer plan. It

was hampered because it operated in secrecy, and no one was certain what the objectives were. A number of lawsuits under the so-called sunshine laws elicited the fact that most of the task force members were government employees. Most of the prominent health economists who had been invited to join the task force defected, and with its support base eroded, this most recent plan was short-lived.

Currently, the future of universal health care under a government single-payer system is uncertain. There is renewed interest because of increasing problems, but a belief persists among elected officials that tackling health care reform is political suicide. Among the latest problems are the steadily increasing numbers of uninsured (reportedly near 40 million) and the failings of managed care that have brought the health system to the verge of chaos. Judging from the past 60 years, it might be predicted that whatever private or public sector solutions are sought, the federal government's role in providing health care, either directly or indirectly, will increase. Medicare will continue to expand, at first perhaps into prescription drug coverage, as will other government programs. Most health economists oppose government-sponsored health care because the very nature in which it is proposed would ensure that it would go the way of Medicare, Medicaid, and other federal health programs that from their inception were designed to be inefficient. Most ideas on the horizon have their incentives in the wrong direction, encouraging higher costs, waste, and even fraud. Still other health economists have a much different perspective and see the health system to be on the verge of collapse. In their view, a federal single-payer plan is ultimately inevitable. The subject of universal health care continues to evoke strong pro and con positions and little certainty.

UNSTRUCTURED CLINICAL INTERVIEW

The clinical interview has long been regarded as a foundational element of psychiatric and clinical psychological practice (Sullivan, 1954; Wiens, 1976). The interview format, of course, affords the clinician the direct opportunity to solicit from the patient salient, firsthand information regarding his or her presenting problems and the exigencies thereof. This assessment information typically proves germane to the ongoing process of case conceptualization (e.g., diagnosis) and the formulation of appropriate intervention strategies (Scheiber, 1994). In addition, under many circumstances the clinical interview involves the interviewer in the process, not just in assessment, but also in implementing de facto interventions (i.e., acting as an agent of salubrious clinical change during the interview itself).

Despite the existence of literally thousands of assessment instruments—personality inventories, symptom checklists, historical reviews, and so forth—in actual clinical practice the interview is still the most frequently employed assessment procedure (Beutler, 1995). Unlike many other assessment methods, the interview requires no additional expense on the part of therapist or patient; further, it may be tailored to meet the unique needs of each individual patient, may be modified to accommodate implicit or explicit temporal constraints, and may subserve the important function of assisting in the development of rapport and understanding between clinician and patient.

There are three distinctive subtypes of clinical interviewing, most commonly referred to as structured, semistructured, and unstructured. In a structured clinical interview, the interviewer proceeds in verbatim fashion through a predetermined list of questions, each of which may be answered by the patient with short, factual responses (Pope, 1979). Because the structured interview has considerable potential to be experienced by both clinician and patient as contrived and inflexible, such an approach is rarely employed in routine clinical practice, and even in research settings it is less frequently employed than is a related, but more flexible format—the semistructured interview. In the semistructured format, the clinician employs a scripted set of initial queries (still asked verbatim) but is permitted to compose ad hoc follow-up questions tailored to the task of obtaining all necessary clinically relevant information. The Structured Clinical Interview for *DSM-IV* (SCID; First, Spitzer, Gibbon, & Williams, 1995), Longitudinal Interval Follow-up Evaluation (LIFE; Keller et al., 1987), and Anxiety Disorders Interview Schedule–IV (ADIS-IV; DiNardo, Brown, & Barlow, 1994) all serve as examples of commonly employed semistructured interviews.

In rather stark contrast, the unstructured interview does not rely on an a priori set of specified questions; instead, the interview content develops as an emergent result of the clinician-patient interaction. Although the clinician may enter the interview with a set of content domains about which he or she might wish to gather information (e.g., the patient's presenting problems, current level of adaptive function, available social support, prominent psychosocial stressors, coping style, characteristic ego defense mechanisms, etc.), the clinician in an unstructured format quite deliberately refrains from *directing* the interviewee through a predetermined list of queries regarding such content. Rather, the clinician affords the client ample license to initiate and specify much of the interview content and the pace of content coverage. The clinician's role in such an interview format may be defined principally as *skillful interaction,* as opposed to the structured interviewer's role of *skillful direction.* It is to be noted, however, that unstructured interviewing, in comparison with more structured interview formats, has received relatively little in the way of

research support vis-à-vis the validity and reliability of the clinical inferences derived therefrom (Segal, Hersen, & Van Hasselt, 1994). Nevertheless, the unstructured interview remains the most commonly employed form of interviewing in the clinical setting (Beutler, 1995).

The unstructured interview format, of course, is closely tied historically to psychoanalytic practice. Within a psychoanalytic conceptual framework, the clinician's creation of an unstructured context is considered to be the essential prerequisite for the patient's subsequent communication of unconscious material (e.g., in the form of so-called transference reactions, free associations, and so forth). It is noteworthy, however, that use of the unstructured interview is not limited to psychoanalytic practice. In fact, unstructured interviewing may be employed by clinicians across the theoretical spectrum, although certainly the focus of the interview will vary somewhat according to the clinician's theoretical orientation. For example, a psychodynamic clinician might show keen interest in the discussion of material regarding the patient's childhood history and familial dynamics (Pope, 1979), whereas a behavior therapist would be more likely to provide subtle reinforcement (e.g., by attending more carefully) for the patient's reporting of specific and detailed information concerning present difficulties and the environmental antecedents and sequelae of such functional problems (Sarwer & Sayers, 1998). The behavior therapist would also likely play a more active role in the interview (e.g., asking more questions) than would her psychodynamic counterpart, while still operating within the broad bounds of the unstructured format by virtue of the deliberate avoidance of predetermined queries.

In the view of many practicing clinicians, the unstructured interview is the format of choice for the efficient gathering of useful clinical information, chiefly due to the extraordinary flexibility associated with the unstructured format. As Johnson (1981) stated, "although haphazard questioning should be avoided, the interview must be loosely enough structured so that the interviewer can pursue avenues of inquiry that present themselves during the course of the interview" (p. 86). Similarly, in order for an interview to be optimally effective, it must be organized around the patient, rather than around a specific psychiatric interview format (MacKinnon & Michels, 1971). Likewise, clinicians from the Rogerian tradition hold that the unstructured format, by virtue of its implicit insistence that the clinician attend to the issues and topics raised by the patient (rather than vice versa), may more easily facilitate the establishment of a positive therapeutic alliance (e.g., Rogers, 1951). However, as we will see, despite the possible intuitive appeal of the aforementioned claims, they have received very little in the way of empirical corroboration.

Format Variables

Unstructured interviewing is a difficult skill to acquire. It is not surprising, therefore, that clinical training programs (e.g., master's and doctoral programs of clinical psychology, counseling psychology, social work, and—less so—psychiatric residency programs) typically devote considerable attention to the development of such skills among their students. Interviewing is typically taught with an overt emphasis on the cultivation of listening skills (as opposed to questioning skills, per se), perhaps because it is not uncommon for the novice clinician to conduct interviews in an ineffectual manner that might charitably be described as a barrage of questions. The acquisition of solid unstructured interviewing skills typically requires considerable practice, in addition to a capacity on the part of the interviewer for critical self-reflection (in order to learn from one's inevitable interviewing missteps) and a recognition of the fact that the interview is based, ultimately, on a human relationship (Johnson, 1981). In an attempt to facilitate the training of interviewing skills, various clinical theorists have subdivided the interview into discrete phases, steps, or objectives.

Harry Stack Sullivan, a seminal figure in both the theory and practice of American psychiatry, was one of the first clinicians to give extensive attention to the interview process. In his still-influential book, *The Clinical Interview* (1954), he described four principal stages characteristic of the unstructured interview (along with the caveat that such stages be recognized as "hypothetical, fictional, abstract, and artificial"). These four stages Sullivan termed the *inception,* the *reconnaissance,* the *detailed inquiry,* and the *termination.* The inception includes the clinician's welcoming of the patient and the establishment of what is to be expected from the interview. The reconnaissance stage consists of questioning regarding the patient's history, social situation, and therapeutic needs. During the inquiry stage, the clinician begins to test various clinically relevant hypotheses, especially those germane to the patient's presenting set of problems. The fourth stage, termination, refers to the delicate process of ending the interview in mutually satisfactory fashion.

A somewhat related, contemporary description of the unstructured interview process is to be found in Shea's (1988) proposed five-phase structural model. This model suggests a broad interview outline that may prove especially helpful for the beginning interviewer and that appears applicable to most forms of unstructured interviewing, regardless of the theoretical context within which the interview occurs. Phase one, the introduction, refers to the initial contact between patient and therapist. During this phase, the therapist may attempt to put the patient at east with conversational small talk and to educate the patient about the interview process itself. Phase two, the opening, entails the clinician's encouraging the patient to provide a first-person account of presenting problems, elicited by a statement such as "Tell me what brought you to therapy." Phase three is the body of the interview. During this phase, the interviewer works to gather relevant information based on material presented during the opening. Such information will

subsequently be used by the clinician in the process of case conceptualization and treatment planning. During the closing phase, the interviewer begins the simultaneous process of summarizing material covered during the interview and communicating the clinician's own conceptualization of the manner in which the patient's problems may be optimally addressed—a process that often helps foster a sense of hopefulness in the patient (Frank & Frank, 1991). The final phase, termination, describes the formal cessation of the interview and the exiting of the patient. Shea's model nicely illustrates the point that although the interview format may remain unstructured (inasmuch as the questions and wording thereof are not planned prior to the session), the interviewer typically retains a general idea of the sequence and flow of the interview.

Relationship Variables

Regardless of its degree of structure, the interview process provides the clinician with an implicit opportunity to cultivate a therapeutic alliance with the patient. Moreover, the flexibility of the unstructured situation permits the therapist considerable latitude to respond empathically to the stated concerns of the patient while also providing the patient with an opportunity to observe the clinician's distinctive interpersonal style in action. What, though, are the actual strategies to be employed by the interviewer in promoting a positive working alliance? On the basis of considerable clinical observation and research evidence, Carl Rogers (1961) suggested a set of general principles that may guide the clinician in such an endeavor, among them (1) maintaining a nonjudgmental attitude toward the patient and toward the material that he or she relates during the interview, (2) viewing the patient with unconditional positive regard, (3) reflecting accurate empathy, and (4) conveying a sense of authenticity and genuineness. In a similar vein, Othmer and Othmer (1994) identified a set of guiding principles that may be employed by the clinician to help facilitate clinician-patient rapport, notably, putting the patient at ease with the interview situation (e.g., by greeting the patient in a warm yet professional manner), determining the source of the patient's suffering and showing appropriate empathy, assessing the patient's own (subjective) understanding of his or her problems, communicating a sense of being on their side, and acting as a credible clinical expert.

Research

Despite the ubiquity of the unstructured interview in clinical practice, it is noteworthy that there is a paucity of research concerning its clinical utility. Nevertheless, a handful of published investigations have some bearing on this issue. Following is a brief summary of the relevant literature.

As noted previously, the unstructured interview is employed primarily as a method of clinical assessment—that is, as a means of gathering information pertinent to case conceptualization (e.g., diagnosis) and treatment planning. But how valid and reliable is the information obtained in the unstructured interview format? With respect to the assignment of *DSM*-based diagnoses, the scant available evidence suggests that unstructured interviews may be inferior to structured and semistructured diagnostic interviews with respect to both the reliability and validity of interview-based diagnoses (Segal et al., 1994; Vitiello, Malone, Buschle, & Delaney, 1990; Widiger, Sanderson, & Warner, 1986; Young, O'Brien, Gutterman, & Cohen, 1987). In fact, it appears that structured interviewing exhibits psychometric properties superior to unstructured interviewing even regarding the assessment of the patient's psychiatric social history (Ferriter, 1993) and treatment expectations (Ruggeri, Dall'Agnola, Agostini, & Bisoffi, 1994). Additional support for the hypothesis of the generally poor psychometric properties of unstructured interviews comes from a recent meta-analysis of the use of structured versus unstructured interview formats in employment selection decisions (McDaniel, Whetzel, Schmidt, & Maurer, 1994). Finally, there is some evidence that the unstructured interviewer's own beliefs and preconceptions may exert a biasing effect on the interview process itself, affecting what the patient is willing to discuss in the ongoing reciprocal process of selecting seemingly pertinent information (Gordon, 1969).

In light of the continued widespread utilization of unstructured interviewing as a principal source of information on which clinical diagnoses are assigned, it is rather puzzling that clinical researchers have given so little attention to clarifying the extent to which such a practice may be regarded as reliable and valid. Certainly, on the basis of the scant available evidence, there is some reason to question the psychometric soundness of such a practice, but it is equally clear that more systematic evaluation is necessary before any unequivocal conclusions may be drawn. Similarly, we are aware of no published investigations of the claim that unstructured interviews are superior to structured interviews in the facilitation of the therapeutic alliance. This would appear, therefore, to be another important domain for future clinical investigation.

V

VALIDITY

Validity refers to the extent to which a test accurately assesses the construct it purports to measure. Essentially, validity has to do with the meaningfulness and usefulness of the specific inferences made from test scores. For a measure of psychoticism, the question of its validity would be whether it actually measures psychotic traits or psychotic behavior. There is an old adage that states a test can be reliable (i.e., stable and consistent) but not valid, but a test cannot be valid without first being reliable. The question of a test's validity is both an empirical issue and a theoretical one. The validity of any psychological test cannot be absolutely established but only relatively established because there is no gold standard of validity in measurement. There are also many different types of validity, including face, content, criterion, and construct validity.

Face validity is perhaps the simplest type of validity. Face validity can refer to a single item or to all of the items on a test, and it indicates how well the item reveals the purpose or meaning of the test item or the test itself. For example, the test item "Recently I have thought of killing myself" has obvious face validity as an item measuring suicidal ideation. The downside of items on tests with clear face validity is that they may be easily manipulated by respondents, either to deny or hide problems or to malinger or exaggerate problems. Some psychometricians appreciate tests that lack face validity but still possess general validity. Tests or items that still measure what they purport to measure but lack face validity are harder for respondents to manipulate.

The *content validity* of a test refers to the adequacy of sampling of content across the construct or trait being measured. Given the published literature on a particular trait, are all aspects of that concept represented by items on the test? Consider an example of conduct disorder in childhood. If a literature search reveals two major aspects of a conduct disorder, namely delinquency and aggression, then the items on the tests should measure these two aspects in relatively equal proportion. Some test makers also rely on experts in that field. The test makers will devise a means of summarizing what the experts claim to be the nature of a particular construct and then create test items to reflect what the experts' consensus was about that construct. Items measuring a trait should appear in equal proportion to what the literature search reveals or what the experts claim about that particular construct.

Criterion validity (also called predictive or concurrent validity) refers to the comparison of scores on a test with some other external measure of performance. The other measure should be theoretically related to the first measure, and their relationship can be assessed by a simple correlation coefficient. Some psychometricians further divide criterion validity into predictive or concurrent validity. With predictive validity, the new test is given to a group of participants who are followed over time to see how well the original assessment predicts some important variable at a later point in time. In concurrent validity (which is far more common), a proposed test is given to a group of participants who complete other theoretically related measures concurrently (at the same point in time). How can a test maker demonstrate concurrent validity if he or she is the first to create such a test? Unfortunately, this is not done as easily. The test maker must use other forms of validity (other than concurrent) if there are no other known measures of that construct. This problem is particularly thorny for diagnostic measures in psychology. Because there are no definitive biological markers and no blood tests used for the diagnosis of any mental disorder, this lack of a so-called gold standard for diagnostic accuracy makes it difficult to assess the criterion-related validity of any psychological test.

Construct validity refers to the extent to which a test captures a specific theoretical construct or trait, and it overlaps with some of the other aspects of validity. This requires a test to be anchored in a conceptual framework or theory that delineates clearly the meaning of the construct, its uniqueness, and its relationship to other variables measuring similar domains. Psychometricians typically assess construct validity by giving other measures of a trait along with the new proposed measure of a trait and then testing prior hypothesized relationships among the measures. In the example of the new Jones Conduct Disorder scale, Jones might also give measures of attention-deficit/hyperactivity disorder (ADHD), altruism, and executive functions deficits (organization and planning problems). Jones might hypothesize that if the new measure of conduct disorder possesses construct validity, then it should correlate positively with ADHD (because the literature suggests a strong comorbidity among the two disorders), correlate negatively with altruism (which might be a clinical intuition without

evidence from the literature), and correlate positively with executive function deficits (also consistent with the literature). Note that the hypothesized relationships include a mixture of what the construct should show a meaningful positive relationship to and show a meaningful negative relationship to. The new measure should also show weak relationships to other constructs that are theoretically unrelated to it (e.g., eye color or depression). The type of relationships found, if they are consistent with expected results, help to establish the construct validity of the new test.

There is no single method for determining the construct validity of a test. Usually, many different methods and approaches are combined to present an overall picture of the construct validity of a test. Besides the correlational approach described earlier, another frequently used method is factor analysis. A factor analysis helps a test maker clarify the underlying nature of a new test, and it can help the test maker in modifying the new test to make it better (e.g., more comprehensive, more consistent with the literature, etc.).

Another method of establishing a test's construct validity is discriminant validity. For example, a group of repeat male juvenile offenders should score higher on the new conduct disorder scale than would a group of choirboys. School bullies should score higher than their victims on the conduct disorder scale. All of these methods and designs should be used to establish the construct validity of a test. A test manual should report all of the evidence for a test's construct validity, and the more evidence there is, the better.

VIDEO: MAJOR APPLICATIONS IN BEHAVIORAL SCIENCE

Video is used in psychology and neuroscience to gather and disperse information and to help people change (behavior, feelings, attitudes) and as experimental stimuli. These uses are summarized here (cf. Dowrick, 1991).

Analyzing and Documenting

The most extensive use of video in behavioral science is to capture and analyze the actions and interactions of humans and other species. Video has been widely used in the analysis of motor activity, nonverbal communication, and social interaction and for medical diagnosis and surveillance. Recently, digital video equipment has replaced high-speed cine film in the analysis of complex movements in dance and athletics. Comparative psychologists have used video to study animal behavior from the courtship of the praying mantis to language development in gorillas.

Video analysis of facial expression is a highly developed methodology that has been extended to social interactions. With enough resources, video allows any level of analysis once a coding system has been operationalized. It is also possible to take video (moving) X rays for medical clarification in such situations as the inability to swallow.

Video can be used in surveillance, such as in sleep laboratories (with infrared lighting) or from cameras mounted in the motor vehicles of drug-influenced drivers. Sometimes video is used for more general documentation, such as tracking clients' progress through treatment.

Educational Videos

Videos, including CDs and DVDs, are often designed for the purposes of instructing and informing. Research into this medium has been unsystematic, although some training packages have been thoroughly evaluated. Most information influencing production (style, length, pace, etc.) comes from the entertainment and public relations industries. A rapidly expanding strategy involves interactive multimedia, in which computer software uses the student's responses to alter exposure to learning materials and tasks. Promising applications can be listed under three broad headings.

The first is classroom education—in schools (e.g., multimedia for learning to read), in universities (e.g., illustrations of attribution theory), and on the job (e.g., supported employment). Applications in this area increasingly include digital technology. The second area is clinical treatment preparation. Patients and family members are shown previews of medical procedures. The third area is lifestyle education, including childhood development and consequences of drug use. Some use, with much promise, exists for special populations (e.g., deaf, physical disabilities).

Peer Modeling

To support people in learning skills, video is widely used to provide demonstrations of effective behavior by a like-person in a like-situation. The range of professional training applications go from divorce mediation to flying an airplane. Other productive areas are social skills, daily living, and sport. The potential for appropriately designed modeling videos for diverse populations is promising but underdeveloped.

Strategies for video-based modeling have not extended much beyond those for live models (similar, multiple, coping). However, there is clear advantage in the potential for repetitive review (with unvarying information), close-ups, slow motion, and so on to the benefit of the learning situation and lower costs.

Self-Modeling

Self-modeling is a procedure in which people see themselves showing only adaptive behavior (Dowrick, 1999). Although video is the best known medium for this procedure, audiotapes, photographs, stories in print, role play, and individuals' imaginations are also used. Researched interventions exist for a wide variety of applications: disruptive behavior, selective mutism, anxiety, Olympic sports, social skills, safety, and others.

The most effective form of self-modeling uses *feedforward,* a term coined to refer to images of desired skills not yet achieved, often created by scripting and editing. For example, a child cannot read independently, but he can point at the words and repeat a phrase at a time; these elements can be videotaped separately and edited to look like realistic independent reading.

A related strategy is *positive self-review,* which refers to watching selectively compiled best examples of skills infrequently or inconsistently achieved. For example, a volleyball player might view videos of her best service, overhead slam, and so on after a full day of many attempts.

Self-modeling videos are typically 2–3 minutes long and reviewed about once a day, for a total of six or more viewings, for maximum effect. They can be reviewed again after 2 or 3 months if a maintenance booster is desired.

Self-Confrontation and Feedback

The practice of video feedback is frequently used, although its theoretical basis remains in dispute. Seeing oneself in personally demanding situations can improve self-assessment. Video feedback is thus applied in many ways: competitive sports, professional skills, interpersonal communication, and so on. It appears to be most effective when the behavior to achieve improvement is clearly indicated and some additional support (e.g., coaching) is provided.

Another value of viewing oneself on video may come from motivational or emotional impact. The effect of seeing a poor performance on video, without being able to undo it, can range from despair and anxiety to increased engagement and determination to succeed. Thus the procedure is risky.

Scene Setting

The use of video to promote discussions, memories, emotions, or judgments is common but understudied in practice. The use of interpersonal process recall (reviewing videotapes to reexamine thoughts and feelings associated with specific actions) has been widely used to teach interviewing and counseling.

The term *triggers* was coined to refer to videos that provoke discussions in group learning experiences. These are typically very short, unresolved vignettes on contentious topics (e.g., child abuse, cultural attitudes). Vignettes are seldom reported in therapy, except some promising uses in social skills training, exposure therapy, and sex therapy. A related use of video is the developmental impact for people (e.g., teens with emotional disturbance, criminal offenders) who take part in scripting and producing their own videos, sometimes airing them on public access television.

Experimental Stimuli

Many research studies mention the use of video vignettes, but the methodological principles are minimally defined. Video content may provide the independent variable (e.g., scowling in one vignette, smiling in another), or video may be contrasted with another medium (e.g., seeing oneself in videos vs. a mirror). It is common to use a single vignette, creating different conditions by labeling (e.g., "she has attention deficit" vs. "she is disruptive") or using different categories of subjects (e.g., experts vs. novices).

Video can even be a dependent variable, as when subjects adjust a distorted image to meet some criterion (e.g., perception of body size).

Conclusion

The potential for using video in behavioral science is ready for another expansion. Improving technology and easier editing, with or without computers, present new opportunities.

VINELAND SOCIAL MATURITY SCALE

Originally developed by Edgar A. Doll, the Vineland Social Maturity Scale represented an early attempt to measure social competence. Doll, in his *Measurement of Social Competence,* defined social competence as "a functional composite of human traits which subserves social usefulness as reflected in self-sufficiency and in service to others" (1953, p. 3). This component of human behavior has also been termed *adaptive behavior,* has been incorporated as a major component in the definition of mental retardation, and has been the focus of considerable measurement effort over the past few decades.

The Vineland evaluates social competence from a devel-

opmental perspective and was normed on males and females from birth to 30 years of age. Assessment using the Vineland typically involves interviewing a person who is familiar with the individual being evaluated (e.g., parent, sibling). The interview is intended to determine the behaviors customarily performed by the target person. In some circumstances observations or direct interviews with the person being assessed are used.

Multiple revisions of the Vineland have been undertaken. Now entitled the Vineland Adaptive Behavior Scales (VABS), it consists of multiple scales including the Classroom Edition, the Interview Edition-Survey Form, and the Interview Edition-Expanded Form. The VABS covers birth through early adulthood and older individuals with disabilities. Third parties still represent major sources of information with the Classroom Edition being completed by teachers and the Interview Edition-Expanded Form being administered to parents. Several assessment domains are addressed, including communication skills, daily living skills, socialization, motor skills, and maladaptive behavior. The VABS samples a variety of behavioral elements, making it useful for a variety of clinical applications. The VABS has also established itself as a useful measurement tool for a broad range of research on developmental status and intellectual conditions ranging from Alzheimer's disease to the effects of social circumstances such as poverty. Although questions have been raised about its norm group, the sample was reasonably large and was drawn nationally. Considerable training is needed to administer the assessment, and care must be taken in scoring and interpretation.

VIRTUAL REALITY EXPOSURE THERAPY

Virtual reality (VR) offers a new human-computer interaction paradigm in which users are no longer simply external observers of images on a computer screen but are active participants within a computer-generated three-dimensional virtual world. Virtual environments differ from traditional displays in that computer graphics and various display and input technologies are integrated to give the user a sense of presence or immersion in the virtual environment.

The most common approach to the creation of a virtual environment is to outfit the user with a head-mounted display (HMD). HMDs consist of separate display screens for each eye, along with some type of display optics and a head-tracking device. This technology integrates real-time computer graphics, body tracking devices, visual displays, and other sensory input devices to immerse a participant in a computer-generated virtual environment that changes in a natural way with head and body motion. For some environments, users may also hold a second position sensor or joystick in their hands, allowing them to manipulate or move around the virtual environment, for example, to use a virtual hand to push an elevator button and ascend.

Exposure therapy is the treatment of choice for many of the anxiety disorders, especially when avoidance is a prominent symptom. Virtual reality exposure therapy (VRE) has been introduced as a new medium of exposure therapy; it is intended to be a component of a comprehensive treatment package and is recommended at the point in therapy at which exposure therapy would be introduced. It has the advantages of allowing time-consuming exposure therapy without leaving the therapist's office and offers more control over exposure stimuli and less exposure of the patient to possible harm or embarrassment. In VRE the therapist makes appropriate comments and encourages continued exposure until anxiety habituates. The patient is allowed to progress at his or her own pace. The therapist simultaneously views on a video monitor all of the virtual environments with which the patient is interacting and therefore is able to comment appropriately. The therapist is present in the room at all times, although she or he is not visible to the patient wearing the HMD, which covers the eyes. For loud virtual environments such as the Virtual Vietnam, the therapist communicates with the patient via a microphone heard over the earphones. VRE has been applied to several anxiety disorders at this point in time.

VRE was incorporated in the treatment of acrophobia (fear of heights) in the first published controlled study to apply VR to the treatment of a psychological disorder (Rothbaum et al., 1995). Subjects were repeatedly exposed to virtual footbridges of varying heights and stability, outdoor balconies of varying heights, and a glass elevator that ascended 50 floors. VRE was effective in significantly reducing the fear of and improving attitudes toward heights, whereas no change was noted in the waiting-list control group. More important, 7 of the 10 who completed VRE treatment exposed themselves to height situations in real life during treatment, although they had not been instructed to do so.

VRE was compared to standard exposure (SE) therapy and to a waiting list (WL) control in the treatment of the fear of flying (Rothbaum, Hodges, Smith, Lee, & Price, 2000). Treatment consisted of eight individual therapy sessions conducted over six weeks, with four sessions of anxiety management training followed by either exposure to a virtual airplane (VRE) or exposure to an actual airplane at the airport (SE). For participants in the VRE group, exposure in the virtual airplane included sitting in the virtual airplane, taxi, takeoff, landing, and flying in both calm and turbulent weather. The results indicated that each active treatment was superior to WL and that there were no differences between VRE and SE. Participants receiving VRE or SE showed substantial improvement on all measures. By the 6-month follow-up, 90% of treated participants had flown since completing treatment. It is important that participants maintained their treatment gains one year following treatment completion (Rothbaum, Hodges, Anderson, Price, & Smith, in press).

VRE has also been adapted for Vietnam combat veterans with posttraumatic stress disorder (PTSD). There are two Virtual Vietnam environments: a virtual clearing and a virtual Huey helicopter. The virtual clearing, often referred to as a landing zone, includes several trees and a bunker surrounded by jungle. The virtual Huey helicopter flies over Vietnam terrain, which includes rice paddies, jungle, and a river. Audio effects include the sound of the rotors (blades), gunfire, bombs, engine sounds, radio chatter, and male voices yelling "Move out! Move out!" Visual effects include the interior of the helicopter in which the backs of the pilot's and copilot's heads are visible, as well as the instrument control panel, and the view out of the side door, including aerial shots of other helicopters flying past, clouds, and the terrain below. The therapist assists the patient in imaginal exposure to his most traumatic memories while immersed in Vietnam stimuli. Preliminary evidence suggests this Virtual Vietnam may hold promise (Rothbaum, Hodges, Ready, Graap, & Alarcon, 2001).

Applications are in place or are currently being developed for the fears of driving, thunderstorms, and public speaking, as well as for several agoraphobic situations such as shopping malls.

VISUAL ILLUSIONS

Illusions have fascinated students of vision for over 2,000 years, but what constitutes an illusion has changed over that period. Almost the whole of visual science is now concerned with illusions—if these are defined as systematic departures of perceptual from physical measurements of a stimulus. But what is the physical description of a stick that is partially immersed in water? It is straight if the stick itself is measured, but not if a photograph is taken of it partially immersed. For this reason (among others), a distinction is made between the distal and proximal stimuli (the physical stimulus and its projection onto the retina). If the light striking the retina (the proximal stimulus) has been transformed in some way, it would be remiss not to incorporate that knowledge in the analysis of its perception. Therefore, psychologists would say that an illusion occurs when there is a mismatch between the proximal stimulus and perception. Theories of illusions abound, and none is widely accepted; a more modest (neuroscience) approach involves relating particular effects to known processes in the visual system.

Illusions are better understood when intermediate measures of stimulus processing are correlated with perception. For example, the radiating spokes seen in Figure 1A can be related to the optics of the eye: Dynamic changes in the axis of transient astigmatism could lead to these effects. The light and dark dots that are visible at the intersections of the lines in Figure 1B have been interpreted in terms of the activity of concentric receptive fields at early stages in visual processing. It is possible to classify illusions according to the levels in the visual system to which the distortions are assigned.

Many cells in the visual cortex respond to lines or edges in specific orientations, and in monkey cortex they have orientation bandwidths of around ± 20 deg of the preferred orientation. Illusions of orientation provide possible matching neural correlates. The horizontal parallel lines in Figure 1C do not appear so when intersected by inclined lines. The perception of orientation must be based on the activity of many orientation selective cells and with interactions between them. The Zöllner illusion could point to a bias in the peak of the distribution by the surrounding contours, mod-

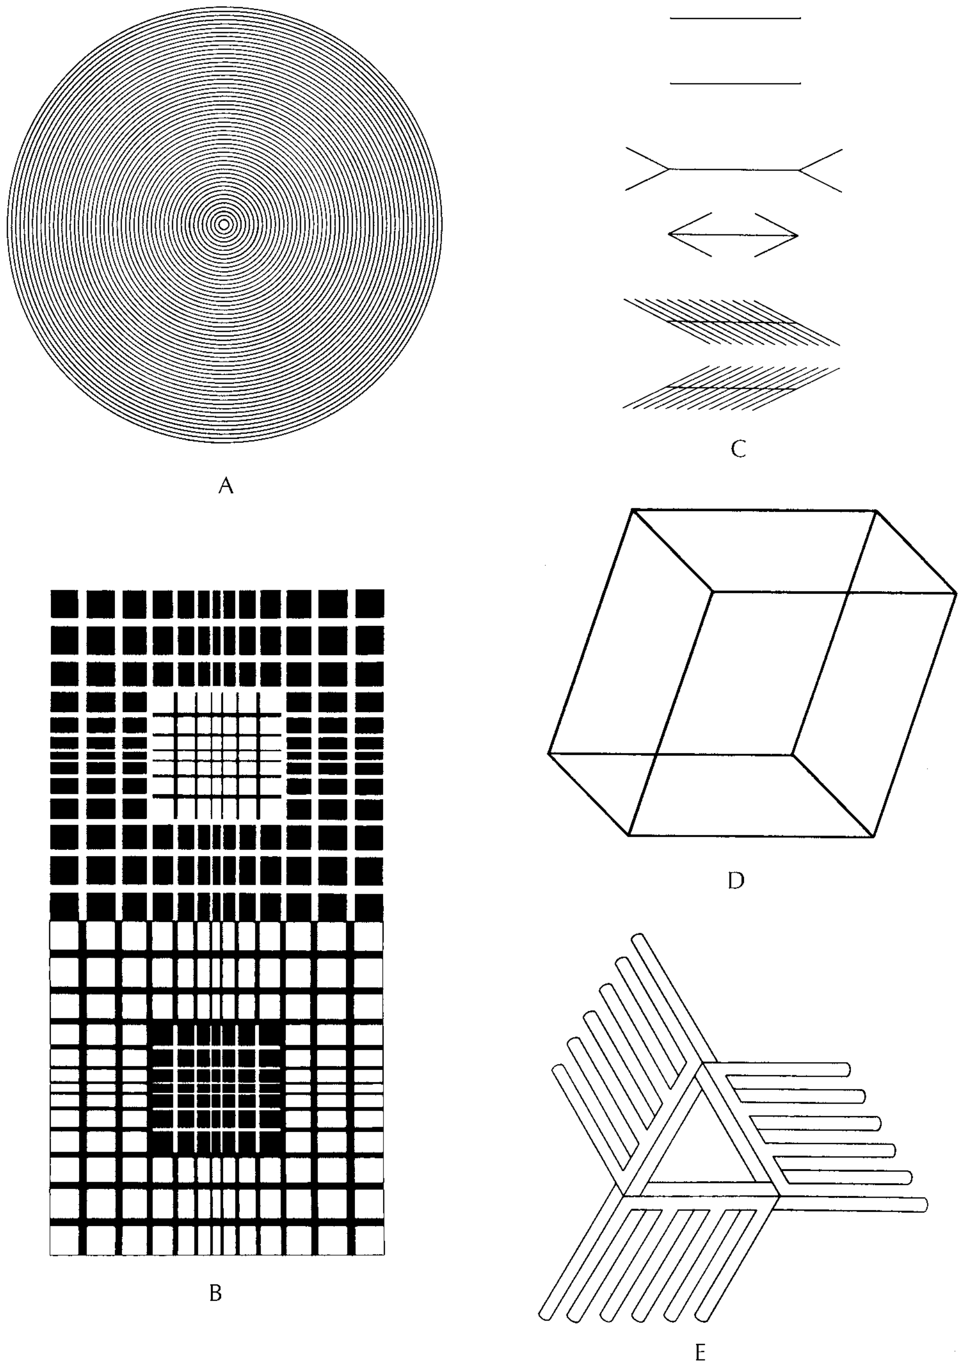

Figure 1. (A) Purkinje's illusion. (B) Hermann-Herring grids. (C) The paired horizontal lines are the same length and parallel in each of the three cases, but their apparent lengths can be modified by attaching fins to the ends (Müller-Lyer illusion), and the apparent orientation can be changed by the directions of the intersecting lines (Zöllner illusion). The gaps between the cross-hatched lines produce illusory contours. (D) Necker rhomboid. (E) Double impossible figure.

ification of the receptive field properties of particular cells by their immediate context, or neural inhibition from the cells with similar receptive field orientations. In addition to the simultaneous biasing of perceived orientation, there are tilt aftereffects: Observation of inclined lines for some seconds results in subsequently viewed vertical lines appearing tilted in the opposite direction. Such simple manifestations are only correlations, and the link between correlation and causation is notoriously tenuous. Increasingly, studies measure both perception and neurophysiology in the same animals so that this link can be strengthened.

Visual illusions are mostly associated with certain fig-

ures produced in the late nineteenth century (Figure 1C). The Müller-Lyer figure provides a compelling illusion of perceived length, and it has been studied experimentally perhaps more than any other, but its basis remains elusive. Visual illusions are generally classified as distortions of orientation or size, and for a long time the former have been taken to provide the better links with neuroscience, but the situation is now changing. Functional distinctions between dorsal and ventral streams of visual cortical processing have been attributed to defining an object's location and identity, respectively. A current reinterpretation is in terms of perception and action: The dorsal stream is said to be concerned with motor control and the ventral with perceptual representation. The difference between the way size illusions look to us and the way we respond to them is taken to support the latter distinction. While our perception is distorted by these patterns, our motor control is not. If sticks were positioned in place of the horizontal lines in the Müller-Lyer figure, observers would adjust their fingers to the appropriate physical length rather than their perceived inequality.

Visual neuroscience is generally concerned with neural and behavioral responses to contours or colors. For the distal stimulus, contours are usually defined as luminance discontinuities, and these can be enhanced by lateral inhibition at early stages of visual processing. However, some stimuli involve seeing discontinuities of brightness where no luminance differences exist. They can be induced by line terminations as in the case of the gaps in the Zöllner figure. Such illusory contours behave much like physical ones—they interact with one another and can produce aftereffects.

Pictures provide allusions to objects, and tricks can be played with the transition from three to two dimensions. Pictures incorporate ambiguities and impossibilities that are rarely or never present in objects. One such ambiguity is the depth that is represented in simple line drawings (Figure 1D): The front face appears to be pointing either down and to the right or up and left. The picture is interpreted as representing a three-dimensional structure, but there is insufficient detail (for occluding contours, perspective convergence, or texture) to define which parts would be near and which far. However, both depth interpretations are not entertained simultaneously: The perception flips from one possibility to the other, so that the apparent depth undergoes reversals. Other pictures are far more paradoxical and have been called impossible. A rectangular rod can be depicted by three lines and a quadrilateral, whereas a cylinder can be described by only two lines and an ellipse (Figure 1E). They are called impossible figures because the solid objects to which they allude could not be constructed.

Pictorial allusions, like ambiguities and impossibilities, are fascinating to figure out, but it is not readily apparent whether there are corresponding links to neuroscience. Indeed, searching for them might point us in the wrong direction because such ambiguities rarely occur with objects. Pictures are complex symbolic stimuli that have a relatively recent history in evolutionary terms. Understanding pictures generally and distortions within them will probably require a more cognitive interpretation.

University of Wade

VISUAL IMPAIRMENT: PSYCHOLOGICAL IMPLICATIONS

Among the most important functions that normally rely on visual capacity are orientation in space as well as the recognition and coordination of behavioral options to be executed in the environment. In humans, cultural techniques such as reading also depend heavily on visual capacity. Vision can also be regarded as a typical environment-related capability; that is, vision is essential for the transaction between the person and his or her environment, especially the physical environment. In contrast, hearing is more concerned with communication (i.e., the social environment).

Clarification of Terms

Terms that are most often, and sometimes interchangeably, used in the literature as well as in the practical field are visual impairment, blindness, legal blindness, and low vision. The term *legal blindness* denotes individuals eligible for government and agency benefits and services. Legal blindness is defined as a visual acuity of 20/200 or less in the better eye with the best correction (normal visual acuity is defined as 20/20, that is, a person with a visual acuity of 20/200 must be at 20 feet to see what a person with normal sight sees at 200 feet distance) or a visual field of no more than 20 degrees (the normal visual field is 175 to 180 degrees). Visual impairment not meeting these criteria can nevertheless interfere with independent functioning and the activities of daily living as well as psychological outcomes, which has been underscored by terms such as *low vision.* Frequently, a visual acuity of 20/70 or less is used as a criterion for low vision; also, difficulty or disability in reading normal newspaper print using the best possible correction has been applied in survey and epidemiology research as a functional definition of low vision.

Prevalence

Although vision loss can occur through the whole life span, it should be noted that about 70% of those affected by visual impairment are beyond the age of 60 years and that about 90% of these have experienced their loss only late in their lives. The positive age correlation persists into very old age:

Whereas around 15% of those 65 and older suffer from visual impairment, the percentage roughly doubles in those aged 85 years and over. Aging minorities and elderly African Americans reveal higher prevalence data due to higher percentages in some other chronic conditions that are associated with visual impairment (e.g., diabetes). In sum, visual impairment is predominantly a challenge for older adults who experience this chronic condition late in life and frequently with an irreversible and progressive course.

Psychological Approaches and Findings

Visual impairment can be seen from a diversity of psychological approaches: Theories of psychological development (psychomotor, cognitive, social) predominantly find application on early life visual impairment. By and large, no severe deviations from normal psychological development should be expected in visually impaired children, and potential deficits present at a certain period in early childhood should always be framed within a broader perspective. For example, compensation techniques such as the development of a haptic frame of reference as well as better use of the hearing system normally are very effective tools for managing a good life into adulthood.

In adulthood, the loss of control probably becomes a major phenomenal feature of vision loss. Theories of stress and coping are especially helpful to consider these consequences of age-related visual impairment. In stress and coping theories, the onset of visual impairment is seen as a permanent stressor that warrants the use of adaptive strategies in order to minimize negative psychological consequences. According to a body of empirical evidence, there can be no doubt that age-related visual impairment is associated with negative consequences in the behavioral and emotional domain. With respect to the former, lower functioning in the activities of daily living and especially the more difficult instrumental activities of daily living (e.g., cooking, shopping, or banking) were found. Regarding the emotional domain, a heightened rate of depression and lower subjective well-being are among the most frequently replicated findings. With respect to the most successful coping strategies in order to deal with these negative consequences, currently the best research answer is that this process is highly individual. Problem-focused coping is not always most effective, and escape strategies may be helpful in some cases as well. Additional variables to explain interindividual differences are comorbidity and subjective evaluations of the vision loss, whereas the objective visual impairment reveals weaker association, particularly regarding negative affective consequences.

Theories of person-environment transactions are important for visually impaired persons of all ages due to the general impact that a vision loss has on the person-environment relation. Nevertheless, person-environment transaction may be particularly worth considering in the later years because it is generally assumed that older adults are more strongly affected by the physical environment in terms of barriers and other hindrances. Person-environment transactions operate, however, on the more subjective level as well. For example, blind elders differed from healthy or mobility-impaired persons in their patterns of place attachment, emphasizing especially the cognitive bonding to their home environment more strongly ("I know my home like the back of my hand"). Also in line with this observation, visually impaired older adults are very creative in person- and environment-related compensation efforts to counteract their visual loss and should thus not be seen as mere pawns of environmental conditions.

Intervention

There are very effective rehabilitation strategies with respect to visual impairment in all periods of the life span. Most critical is training in orientation and mobility as well as training in the performance of day-to-day tasks. Both of these skills are very important in maintaining the highest possible level of independent functioning and autonomy; self-help groups also contribute significantly to the maintenance of rehabilitative success and to coping with the daily challenges caused by the vision loss. However, there is reason to assume that comprehensive ophthalmological rehabilitation, which includes the best visual correction aids as well as the systematic improvement of everyday competence, is broadly applied in the earlier years but still not the rule in the later years of life. Among the reasons for this are the negative image of old age, information deficits in both patients and their doctors, and the simple fact that often no rehabilitation site is readily accessible (e.g., for elders living in rural areas). Probably, this situation is still more unsatisfactory with respect to African American older adults and the elderly from minority population groups. In any case it is important to acknowledge that rehabilitation can be very effective with older adults as well, with the clear consequence of a significant and persisting increase in independence and general quality of life.

VOCABULARY TESTS

The 1994 *Tests in Print IV* listed 40 English vocabulary tests (some being out of print). But these lists are only the tip of the iceberg. Along with vocabulary subsections of nu-

merous intelligence and achievement tests are various verbal tests with high correlations with vocabulary, which require knowledge of words and which measure much the same function: verbal analogies, same-opposite, synonyms, verbal classification, and the like.

Vocabulary tests have many attractions. If it can be assumed that all respondents have grown up in the same general environment and have had similar opportunities to acquire words, vocabulary scores tend to reflect aptitude. However, much instruction is directed toward acquiring concepts in a special area, so that growth in vocabulary is an important aspect of growth in knowledge. Vocabulary is a basic component of reading and writing skills, and it is a prerequisite for many forms of intellectual endeavor.

The high intercorrelations of vocabulary items result in high reliabilities, both by internal consistency and by alternate forms. Empirical validities in situations requiring intellectual abilities also tend to be high because many intellectual activities are almost synonymous with the manipulation of verbal concepts.

P. H. DuBois

VOCATIONAL REHABILITATION

The first Vocational Rehabilitation Act (Public Law 236) in the United States was passed by the Congress on June 2, 1920. This act placed a heavy emphasis on vocation and defined rehabilitation as "the rendering of a person disabled fit to engage in a remunerative occupation."

In theory, then, vocational rehabilitation would be directed to individuals disabled in some way and would be the endeavor of choice for those of incapacity. It would be distinguished from similar undertakings designed with initial training as a goal—such endeavors as career development, vocational guidance, and job training. In practice, however, many disabled persons select from available resources to meet their personal goals, often without regard to such formal definitions or the professionals' intentions.

Personal practices serve to obscure statistical trends and leave definitions imprecise. They occur not without reason, however. They reflect practical considerations. An individual might choose one program over another because it is closer geographically. The stigma associated with vocational rehabilitation, and the disability giving rise to its need, may represent another reason. S. Olshansky suggested that the disabled person often suffers from not one but a variety of types of stigma—relating to physical appearance, stereotypical ideas associated with receiving public assistance, and even attitudes regarding race, color, or religion. As medicine and science continue to produce results that increasingly prolong life, vocational rehabilitation may be called on more and more to contribute to the quality of that life.

WALDORF EDUCATION

Also known as Steiner education, Waldorf education is based on the philosophy of Rudolf Steiner (1861–1925), an Austrian scientist and scholar who was asked to create a school for the children of the workers at the Waldorf-Astoria cigarette factory in Stuttgart, Germany. The first school was organized in 1919, and the movement has since become international with more than 800 schools worldwide.

Teaching is based on Steiner's conception of humans as spiritual beings with repeated earthly lives. Thus, a child is neither a blank slate to be filled with knowledge nor an animal to be civilized, but is viewed by the teacher as bringing undisclosed potentials in various stages of development. The task of education is to allow these various potentials to develop to their full capacities.

Steiner's view of child development holds that the time at which a subject is introduced, as well as the manner in which it is presented, is of utmost importance. The curriculum integrates the arts, sciences, and humanities, and teaching is done from an artistic point of view, taking into account that individuals learn at different rates and in different ways. The stress of Waldorf education is on the development of the whole human being—socially, artistically, physically, and intellectually.

Waldorf schools may begin with a nursery class and go through high school, depending on the particular school. Following the preschool and kindergarten years, a class teacher begins with a group of first graders and, ideally, continues with the group through eighth grade, supported by various specialist teachers. In high school, each class has a sponsor, and all subjects are taught by specialists. There is no principal or head, but all pedagogical decisions are made by members of a college of teachers who share responsibility for the curriculum and program. Teacher training begins with at least two years of postgraduate work at Waldorf institutes. Professional development continues at weekly faculty meetings and yearly regional conferences.

WEBER'S LAW

On the basis of experiments with stimuli of pressure, lifted weights, and visual distance (line lengths), along with reported observations of others, Ernst Heinrich Weber (1795–1878), professor of anatomy at the University of Leipzig, concluded that rather than perceiving simply the difference between stimuli being compared, humans perceive the ratio of the difference to the magnitude of the stimuli. A similar finding had already been made by the French physicist and mathematician Pierre Bouguer (1698–1758) for visual brightness. Gustav T. Fechner (1801–1887), formerly a student of Weber's and later also a professor at the University of Leipzig, translated this conclusion into the familiar mathematical form used today. Thus, Weber's law is usually given as either $\Delta I/I = k$ or $\Delta I = kI$ where ΔI is the change required for a just noticeable difference (JND) in stimulation, I is the stimulus magnitude, and k is a constant for the particular sense. The value of k is termed the Weber ratio. This second formulation shows more clearly the proportional change in stimulation required for a JND. If, for example, the stimulus magnitude is doubled, the amount of change required for a JND is also doubled.

Over the years since Weber's formulation, it has been observed that k is not strictly constant over the entire stimulus range but increases for low and high intensities. It is, however, valid for a large range of intermediate intensities for the various senses.

Representative values of the Weber ratio for intermediate ranges include the following: brightness, 0.02–0.05; visual wavelength, 0.002–0.006; loudness (intensity measure), 0.1–0.2; auditory frequency, 0.0019–0.035; taste (salt), 0.15–0.25; smell (various substances), 0.2–0.4; cutaneous pressure, 0.14–0.16; deep pressure, 0.013–0.030; visual area, 0.06; line length, 0.04.

WEIGHT CONTROL

Obesity has become a global epidemic. Twenty-seven percent of American adults are obese, and an additional 34% are overweight. The prevalence of overweight children has doubled in the last 20 years. Paradoxically, this has occurred while there have been major scientific, medical, and commercial efforts to develop effective means of weight control. One limitation is that these methods have been based on a medical model that emphasizes causes and remedies for individuals. More recently, obesity is considered a public health crisis that demands innovative public policy interventions. This chapter highlights advances in treating obesity, the important issue of stigma, and suggestions for public policy research.

Obesity is a difficult condition to treat. The most optimistic estimates are that 25% of people lose weight and keep it off, leading some experts to emphasize prevention. Yet even if prevention becomes a major priority, the vast numbers of people already overweight deserve compassion and effective care. A number of treatments have been examined.

Commercial and Self-Help Programs

Diet books, community-based self-help groups, and commercial weight loss programs are the most prevalent but least tested approaches to weight control. Consumers and professionals are left to guess about their safety and effectiveness. The Federal Trade Commission has called for commercial weight loss programs to disclose information about the results of treatment, so in the future consumers may be able to make educated decisions about choosing one of these approaches.

Group Behavioral Treatment

Many universities and hospitals offer professionally led group behavioral treatment for obesity, consisting typically of 16 to 20 weekly meetings. Key components are food records, monitoring of physical activity, behavioral strategies to prevent overeating, and cognitive strategies to promote effective coping with stressors and eating triggers. Calorie prescriptions are given, and increasing both programmed and lifestyle physical activity is strongly emphasized. The meetings provide social support and encouragement.

The results of these treatments are well documented; a 20-week program typically results in a 9% weight loss (i.e., 8.5–9.0 kg). Without further treatment, clients typically regain one third of this weight in a year and continue regaining weight over time. A priority in these programs is helping clients recognize the benefits of 5–15% weight losses and facilitating maintenance of weight loss over time.

Very-Low-Calorie Diets and Portion Controlled Diets

A more intensive approach is the liquid very-low-calorie diet (VLCD), which provides 400 to 800 kcal per day. Clients lose twice as much weight initially compared to traditional behavioral treatment, but they regain weight more quickly. At 1-year follow-up, the two approaches have comparable results.

One challenge in weight control is measuring and calculating the calories of foods, so some studies have assessed the effect of providing clients with prepackaged meals. Clients adhere better to low-calorie diets when food is provided than when using a self-selected menu.

Medication

Two medications are currently approved by the FDA for weight loss and maintenance, sibutramine (Meridia) and orlistat (Xenical). Average weight loss with medication alone is around 7–8% at one year, which is comparable to behavioral group treatment. Combining sibutramine with behavioral treatment improves outcome to the range of 10–15%.

Maintenance of Weight Loss

Maintaining weight loss is difficult. Historically, maintenance has been evaluated by providing an intervention, measuring weight loss, and then telling patients to continue making changes on their own and measuring weight loss again at follow-up. If people regain weight, some believe the treatment failed. An alternate view is that treatment *did* work, which is proven by the fact that clients gained weight when it ended. The challenge is finding treatment approaches that are innovative and flexible enough to encourage adherence over the long term.

Obesity is a chronic disorder like diabetes, not a curable condition like an ear infection. A chronic care model, however, conflicts with the desire of many overweight individuals to lose weight quickly and then forget about vigilance. Most successful maintainers continue thinking carefully about food and exercise for the rest of their lives.

Physical Activity

Professionals debate diet approaches, but there is clear consensus that physical activity is central to weight control and leads to benefits apart from weight loss. There is clear

documentation that physical activity level is the best predictor of long-term weight control. Other findings suggest that exercising at home leads to better adherence than does going out to a center and that exercising in several small bouts (i.e., 10 minutes) is just as effective as exercising in one longer bout (i.e., 40 minutes). Lifestyle activity (e.g., taking stairs instead of the elevator, parking at the far end of the lot, walking rather than driving to destinations) is as effective as programmed exercise in increasing cardiovascular fitness.

Recent research raises the possibility that people can be fit at any size and that being fit and fat is better than being unfit and normal weight. This is a helpful concept, as it provides incentive for all individuals to increase their level of physical fitness, regardless of its impact on weight and body size. Increasing activity may be easier than losing weight; hence, some in the field believe that activity should be emphasized over weight loss.

Surgery

Surgery may be the best treatment option for people with considerable weight to lose. The two most common procedures are gastric bypass and vertical banded gastroplasty. These procedures result in weight losses in the 25–30% range, which is associated with significant improvements in medical conditions. These procedures seem to be gaining popularity, and further research is needed on how best to evaluate candidates and identify predictors of successful outcomes. Laparoscopic procedures are technically complicated but can greatly reduce surgical complications and speed recovery.

Different treatments work for different people, so it is unlikely that one best treatment will ever emerge. A more fruitful avenue for research may be to search for the best fit between individuals and programs.

Stigma of Obesity

Obesity is a highly stigmatized condition, and obese individuals experience bias and discrimination in many domains of life, including education, employment, and access to medical care. Some argue that the stigma of obesity serves as an incentive for people to try to lose weight. This is faulty logic—if social pressure to be thin worked, we would not have an obesity epidemic. A climate of blame and criticism not only makes weight loss more difficult but also can lead to emotional distress and further eating disturbance. Research is needed on how to ameliorate the stigma of obesity and provide effective coping methods to those who experience it.

Public Policy Approaches

While individual treatments may work for specific people, we believe that reversing the obesity epidemic requires public policy changes that will influence the population's diet and physical activity. The following ideas have been proposed: (1) Regulate food advertising aimed at children; (2) prohibit fast foods and soft drinks from schools; (3) subsidize the sale of healthy foods; (4) tax unhealthy foods; and (5) provide resources for physical activity. The impact of these policy changes on the health of a community is worthy of further study.

Conclusion

Obesity, along with the poor diet and inactivity that cause it, are major contributors to disease. Obesity is now associated with more chronic illness and greater health care costs than is smoking. The nation must be bold in its response to the epidemic, or the problem will grow worse. Prevention must be a priority, but safe and effective treatments must be available to both adults and children who struggle with their weight.

WERNICKE-LICHTHEIM MODEL OF LANGUAGE PROCESSING

The functional-anatomical model of language processing formulated by Wernicke and Lichtheim in the late 19th century has provided a useful introduction to aphasia for generations of clinicians. Thirteen years before Wernicke's famous monograph, Broca had revolutionized the study of aphasia by linking speech production deficits to frontal lobe damage (Broca, 1861). Wernicke brought these observations together with new data from aphasic patients with temporal lobe lesions, providing the first neuroanatomical account of both language comprehension and production (Wernicke, 1874). Lichtheim's expanded version of this model was influential because of the diagrammatic clarity with which it was able to predict aphasia syndromes from isolated lesions in functional centers or pathways linking the centers (Lichtheim, 1885; Table 1 and Figure 1).

Wernicke Aphasia

Wernicke's area, marked A in the diagram, is the center containing auditory word forms (*Wortklangbilder*). These word forms (the phonological lexicon in more recent terminology) contain information about the sounds of words, essential for decoding speech sound input and for guiding the production of words. Damage to A thus causes impaired speech comprehension as well as incorrect selection or sequencing of phonemes during speaking (phonemic para-

Table 1. Aphasia Syndromes

	Lesion Site				
Syndrome	A Wernicke	M Broca	A-to-M Conduction	A-to-B TC Sensory	B-to-M TC Motor
Spontaneous speech	paraphasic	nonfluent	paraphasic	paraphasic	nonfluent
Spontaneous writing	paragraphic	nonfluent	paragraphic	paragraphic	nonfluent
Naming	impaired	impaired	paraphasic	anomic	anomic
Repetition	paraphasic	nonfluent	paraphasic	nl	nl
Reading aloud	paraphasic	nonfluent	paraphasic	impaired	nl
Auditory comprehension	impaired	nl	nl	impaired	nl
Written comprehension	impaired	nl	nl	impaired	nl

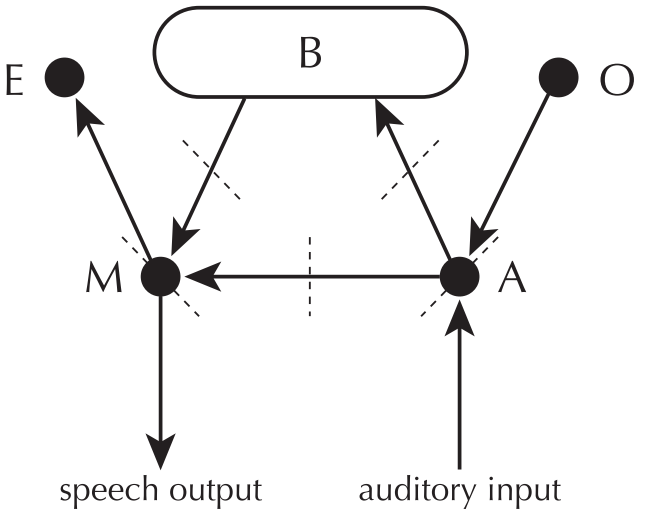

Figure 1. Wernicke-Lichtheim model of language processing.

phasia). Repetition, which requires both speech sound decoding and production, is also impaired, typically with severe paraphasia. In the classical version of the model, the sound images of words being read must be activated by input from the visual center (center O in the diagram) before reading comprehension can occur, and the sound images of words one intends to write are used to guide the motor images used for writing (stored in center E in the diagram). Thus, damage to A also causes alexia and paragraphia. The deficits resulting from a lesion in A are collectively called Wernicke aphasia.

Wernicke localized A to the left superior temporal gyrus (STG). Later authors held widely varying views on the location of Wernicke's area, including some for whom the area encompassed middle temporal, angular, and supramarginal gyri as well as STG (Bogen & Bogen, 1976). A strongly localizationist view, originated by Liepmann, Kleist, and others and popularized in recent times by Geschwind and his students, places A in the posterior STG, particularly in the planum temporale or posterior dorsal STG (Geschwind, 1971). Lesions restricted to the left planum temporale appear to cause only the paraphasic speech component without comprehension disturbance or alexia (Benson et al., 1973; Kleist, 1962). Patients with Wernicke aphasia, including the patients reported by Wernicke himself, have had large lesions extending well beyond the STG (Damasio, 1989; Henschen, 1920–1922; Wernicke, 1874). Comparative studies in nonhuman primates and functional imaging data from humans strongly implicate the posterior STG in auditory functions (Binder, Frost, Hammeke, Rao, & Cox, 1996; Galaburda & Sanides, 1980); this region is thus no longer considered a center for multimodal language processing but probably participates in the sensory analysis of complex sounds, including speech.

Broca Aphasia

A second main component of the model is Broca's center for motor word images (*Wortbewegungsbilder,* marked M in the diagram), which contains motor programs used for movement of the vocal apparatus during speech. Damage to M causes impaired speech production without affecting comprehension. The speaking deficit may be extreme, with complete or nearly complete mutism, or speech may be effortful and nonfluent, with a marked decrease in the length of phrases and the rate of word production. Because M is a final common output node for all speech behaviors, repetition, naming, and reading aloud are all similarly affected. Lichtheim believed that writing movements also depend on input from M; thus, inability to write is often considered a feature of the syndrome. The deficits resulting from a lesion in M are collectively called Broca aphasia. Broca and other early aphasiologists localized M to the pars opercularis of the left inferior frontal gyrus (Brodmann's area 44), but later authors have variously included pars triangularis (area 45) and ventral premotor cortex (area 6) in the definition of Broca's area. Lesions restricted to the left pars opercularis do not cause the full syndrome, but rather a transient deficit of articulation without writing or naming disturbance (Alexander, Benson, & Stuss, 1989; Mohr et al., 1978). Patients with Broca aphasia, including the patient reported by Broca himself, typically have large lesions extending into insula, sensorimotor cortex, parietal operculum, and middle frontal gyrus (Mohr, 1976).

Conduction Aphasia

Damage to connections between A and M also cause impairment of speech production, a syndrome known as conduction aphasia. Comprehension remains intact because A is spared, and speech remains fluent and well-articulated because M is spared. Although Wernicke predicted that such a lesion would cause difficulty producing whole words (anomia), patients with conduction aphasia show instead a disturbance characterized by phonemic paraphasia (Kohn, 1992). Emphasis is often placed on repetition deficits in conduction aphasia, but the same errors typically occur in all speech output tasks. The concept of conduction aphasia as a disconnection syndrome led to the popular view that the critical lesion is in white matter (external capsule and/or arcuate fasciculus) connecting superior temporal to inferior frontal cortex. Evidence for such a localization is scant, however, and typical patients with the syndrome have cortical lesions affecting the posterior STG, posterior insula, or parietal operculum (Benson et al., 1973; Damasio & Damasio, 1980; Kleist, 1962).

Transcortical Aphasia

A third main component of the model is the concept field (*Begriffsfeld*), described as a widely distributed, bihemispheric system containing information about the polysensory properties of objects (center B in the diagram). Comprehension is achieved when the auditory word form makes contact with this polysensory information, while speech production requires that the polysensory concepts activate corresponding motor word images. Because of its widely distributed nature, the concept field could not be damaged by a focal lesion. Focal lesions, however, could sever connections between the concept field and more focal language centers, causing the so-called transcortical syndromes. Repetition is normal in such cases because the A-to-M circuit is intact. Lesions between A and B prevent activation of concepts by auditory word images, causing impaired auditory and written word comprehension with intact repetition. This syndrome is known as transcortical sensory aphasia and is usually caused by damage to the posterior ventrolateral left temporal lobe (posterior middle or inferior temporal gyri) or angular gyrus (Alexander, Hiltbrunner, & Fischer, 1989). Lesions between M and B prevent activation of motor speech centers by concepts, causing nonfluent speech with intact repetition. This syndrome is known as transcortical motor aphasia and is caused by damage to the left middle frontal or superior frontal lobe (Alexander, Benson et al., 1989; Rapcsak & Rubens, 1994). Brain regions in which lesions cause transcortical aphasia have recently been implicated in operations involving verbally encoded semantic knowledge (Binder et al., 1997; Damasio, Grabowski, Tranel, Hichwa, & Damasio, 1996; Démonet et al., 1992; Vandenbergh, Price, Wise, Josephs, & Frackowiak, 1996). The deficits observed in transcortical aphasia may thus be due to direct damage to, rather than disconnection of, these knowledge retrieval systems.

Current Status of the Model

Many advances have been made since the 19th century in our understanding of language processing, and it is not clear that the Wernicke-Lichtheim model in its simple form can accommodate this information. For example, the model has almost nothing to say about syntactic processes or about how spoken or written nonsense words ("brillig," "slithy," "toves") are perceived and pronounced. Empirical observations not accounted for include a variety of context effects in letter and phoneme perception, spared language abilities in auditory or visual modalities, comprehension disturbances in patients with frontal lesions, word frequency effects and short-term memory phenomena in conduction aphasia, spelling regularity and lexicality effects in reading and writing, category-specific naming and comprehension disturbances, and so on. Underlying these difficulties is the fact that the model itself contains little in the way of explicit detail regarding how various transformations—sound to word, print to word, word to concept, concept to word, word to motor sequence—are actually accomplished.

The model has not been entirely abandoned, however, for two reasons. First, the enormous amount of data from modern aphasiology, functional imaging, and cognitive linguistic research has yet to be integrated in a widely-accepted, comprehensive alternative. Second, the range of models employed in the clinical setting may be limited to those that can be readily communicated to students in a diagrammatic or tabular format (Table 1). The Wernicke-Lichtheim model, particularly in its current simplified form, thus continues to serve a useful role as initial common ground for the interested student of aphasiology.

WISDOM

Some Historical Background to the Study of Wisdom

Since the beginnings of human culture, wisdom has been viewed as the ideal endpoint of human development (Baltes & Staudinger, 2000). Historically, wisdom was conceptualized in terms of a state of idealized being, as a process of perfect knowing and judgment (as in King Solomon's judgments), or as an oral or written product such as wisdom-related proverbs. It is important to recognize that the identification of wisdom with individuals (e.g., wise persons), the predominant approach in psychology, is but one of the ways by which wisdom is instantiated. Wisdom is considered an ideal that is difficult to be fully represented in the isolated individual.

Two main lines of argument have been in the center of the historical evolution of the concept of wisdom: the distinction between philosophical and practical wisdom, and the question of whether wisdom is divine or human. Archeological-cultural work dealing with the origins of wisdom-related texts in China, India, Egypt, Old Mesopotamia, and the like has revealed a cultural and historical invariance with regard to wisdom-related proverbs and tales. This relative invariance suggests that the body of knowledge and skills related to wisdom have been culturally selected because of their adaptive value for humankind.

Psychological Approaches to the Definition of Wisdom

A first approach to the definition of wisdom from a psychological perspective is its treatment in dictionaries. The *Oxford Dictionary,* for instance, includes in its definition of wisdom, "Good judgment and advice in difficult and uncertain matters of life."

In a next step, psychologists further specified the content and formal properties of wisdom-related phenomena. G. Stanley Hall and other writers emphasized that wisdom involves the search for the moderate course between extremes, a dynamic between knowledge and doubt, a sufficient detachment from the problem at hand, and a well-balanced coordination of emotion, motivation, and thought. In line with dictionary definitions, such writings refer to wisdom as knowledge about the human condition at its frontier, knowledge about the most difficult questions of the meaning and conduct of life, and knowledge about the uncertainties of life—about what cannot be known and how to deal with that limited knowledge (for an overview, see Sternberg, 1990).

Implicit (Subjective) Theories about Wisdom

Most empirical research on wisdom in psychology so far has focused on further elaboration of the definition of wisdom. Moving beyond the dictionary definitions of wisdom, research explored the nature of everyday conceptions or implicit (subjective) theories of wisdom.

From this research on implicit theories of wisdom (for a review, see Sternberg, 1990), it is evident that people in Western samples hold fairly clear-cut images of the nature of wisdom. Four findings are especially noteworthy. First, in the minds of people, wisdom seems to be closely related to wise persons and their acts as carriers of wisdom. Second, wise people are expected to combine features of mind and character and balance multiple interests and choices.

Third, wisdom carries a very strong interpersonal and social aspect with regard to both its application (advice) and the consensual recognition of its occurrence. Fourth, wisdom exhibits overlap with other related concepts such as intelligence, but it also carries unique variance.

Explicit Theories and Assessment of Wisdom

A more recent line of empirical psychological inquiry on wisdom addresses the question of how to measure behavioral expressions of wisdom. Within this tradition, three lines of work can be identified: (1) assessment of wisdom as a personality characteristic, (2) assessment of wisdom in the Piagetian tradition of postformal thought, and (3) assessment of wisdom as an individual's problem-solving performance with regard to difficult life problems.

Within personality theories, such as Erik Erikson's, wisdom is usually conceptualized as an advanced if not the final stage of personality development. A wise person is characterized, for instance, as integrating rather than ignoring or repressing self-related information, by having coordinated opposites, and by having transcended personal agendas and turned to collective or universal issues.

Central to neo-Piagetian theories of adult thought is the transcendence of the universal truth criterion that characterizes formal logic. This transcendence is common to conceptions such as dialectical, complementary, and relativistic thinking. Such tolerance of multiple truths, that is of ambiguity, has also been mentioned as a crucial feature of wisdom.

There is also work that attempts to assess wisdom-related performance in tasks dealing with the interpretation, conduct, and management of life. This approach defines wisdom as "an expert knowledge system in the fundamental pragmatics of life permitting exceptional insight, judgment, and advice involving complex and uncertain matters of the human condition" (Baltes, Smith, & Staudinger, 1992).

The body of knowledge and skills associated with wisdom as an expertise in the fundamental pragmatics of life entails insights into the quintessential aspects of the human condition, including its biological finitude and cultural conditioning. More specifically, wisdom-related knowledge and skills can be characterized by a family of five criteria: (1) rich factual knowledge about life, (2) rich procedural knowledge about life, (3) life span contextualism, (4) value relativism, and (5) awareness and management of uncertainty (see Baltes et al., 1992, for an extensive definition).

To elicit and measure wisdom-related knowledge and skills, in this approach participants are presented with difficult life dilemmas such as the following: "Imagine that a good friend of yours calls you up and tells you that he/she can't go on anymore and has decided to commit suicide. What would you be thinking about; how would you deal with this situation?" The five wisdom-related criteria are used to evaluate these protocols.

Part of the Berlin paradigm also is a general framework outlining the conditions for the development of wisdom. The empirical work based on this ontogenetic model and the measurement paradigm produced outcomes consistent with expectations. It seems that wisdom-related knowledge and judgment emerge between the age of 14 and 25 years; afterward, growing older is not enough to become wiser (Staudinger, 1999). However, when age was combined with wisdom-related experiential contexts, such as professional specializations specifically involving training and experience in matters of life, higher levels of performance were observed. In line with the historical wisdom literature, which portrays wisdom as the ideal combination of mind and virtue, it was found that wisdom-related performance was best predicted by measures located at the interface of cognition and personality, such as a judicious cognitive style, creativity, and moral reasoning.

Is There Wisdom-Related Potential?

Given the fact that wisdom-related performance had been successfully operationalized, the question arose whether it was possible to increase wisdom-related knowledge and judgment. It should also be noted that, not surprisingly, the overall level of wisdom identified was below or around the theoretical mean of the scale, thus leaving a lot of room for improvement.

One study took into account that higher performance levels may be found if two minds can interact before responding to the wisdom dilemma. And indeed, when two individuals usually interacting about life problems in everyday life had a chance to do so before they individually responded to wisdom tasks, the performance level was increased by one standard deviation (Staudinger & Baltes, 1996). The second study focused on one of the five wisdom-related criteria, value relativism. Participants were trained to think about life problems located at different regions of the world. At posttest, participants trained in the knowledge-activating strategy outperformed the control group by more than half a standard deviation (Baltes & Staudinger, 2000).

Conclusion and Future Directions

The concept of wisdom represents a fruitful topic for psychological research. The study of wisdom emphasizes the search for continued optimization and the further evolution of the human condition, and in a prototypical fashion, it allows for the study of collaboration among cognitive, emotional, and motivational processes. We expect that future research on wisdom will be expanded in at least three ways: (1) the further identification of social and personality factors and life processes relevant for the ontogeny of wisdom, (2) the exploration of wisdom as a meta-heuristic aimed at orchestrating mind and virtue toward human excellence, and (3) the contribution of wisdom research to building a psychological art of life.

WORK AND PLAY

The technological character of advanced modern civilizations has tended to segregate work and play. A further extension of these segregations is to differentiate the motivations for work and play. This suggests that work is characterized by activities engaged in for the purpose of staying alive and that play refers to activities engaged in for their own sake. E. S. Bordin has proposed that work and play can be seen as involving various combinations of effort, compulsion, and spontaneity.

Effort and compulsion are intimately related. The greater the effort and the longer it endures, the stronger the pressure toward cessation and rest becomes. What sustains effort against the accumulating counterpressure is inner interest and involvement or externalized threats of punishment or annihilation, which, in turn, can be internalized and experienced as an inner compulsion, for example, to stay alive. Spontaneity refers to that element of interest, self-investment, and self-expression that transforms an effortful performance that might have been experienced as alienated toil into a creative, joyful self-expression. This transformed activity epitomizes play.

Work and Play in Childhood

The bulk of the observation of play has been directed toward the immature. In young animals and children, observers stress the excess energy expended and the usefulness of play as a means toward mastery. Therapists working with children utilize this concept of play. Similarly, children are seen as using play to try out and prepare for anticipated adult roles.

The history of education has been marked by concern with preserving spontaneity concerned with maintaining appropriate levels of directed effort. Observers of children's play have noted that the fluid, spontaneous play of the young child soon gives way to formalizations of rules, which introduces restraining boundaries to spontaneity. The physical and intellectual development of the child is accompanied by more sophisticated play with its demands for mastery. Thus, growth and maturation are accompanied by ever-increasing participation by compulsion and effort. Play has become more than a simple joyful expression of energy in which effort is background.

Work and Play in Vocation

Virtually all persons face the necessity of securing the material means of staying alive or for additional comforts. In work-intensive societies, there was more room for men and women to mix the process of working for a livelihood with flexibility for self-expression. Our modern machine-dominated technological society challenges the preservation of these elements in work.

Is there any way to protect against work as alienated toil? Marxist philosophers such as Herbert Marcuse argue that under socialism in which the worker feels in control of the larger process of production, the greater economies in productivity afforded by the utilization of the machine can be converted into greater free time, making possible the assimilation of work into play. He argues that the experience of alienated labor is dictated by the excess repression exerted by capitalism to maintain that economic system.

Psychologists and industrial sociologists point out that many highly skilled jobs and professions require and permit long-term commitments and the flexible expressions of self that mix the compulsion, effort, and spontaneity marking the fusion of work and play. Research on personality development and the psychological characteristics and requirements associated with various occupations and occupational families has provided the base for helping individuals seeking vocational commitments to channel their choices toward optimal reconciliations of the wishes for material returns with their desires for satisfaction in work.

There remains the question of whether this can apply to all jobs. The Marxist answer accepts the antihumanistic element in the machine-human interface and only seeks to limit its duration. R. Blauner found that the worker's relation to the technological organization of the work process and the social organization of the factory determines whether he or she experiences a sense of control rather than domination, a sense of meaningful purpose rather than isolation, and a sense of spontaneous involvement rather than detachment and discontent. These views have spawned many efforts through job enlargement, job rotation, or drastic redesign to achieve for workers desirable levels of intrinsic satisfaction in their work life.

Work and Play in Leisure and Retirement

Surveys of workers' use of nonwork time finds them engaged in second jobs, educational activities, household chores, and child care. Some of this reflects the same economic pressures that make work a necessity. But these data also suggest that a major motivation in leisure time activity is not the removal of effort, but relaxation of the pressure of compulsion.

WORKING MEMORY

Everyday cognitive tasks, such as language comprehension, reasoning, and decision making, often require one to keep relevant information in mind while processing other information. For example, mental arithmetic requires keeping track of the intermediate results from relevant computations and integrating them to reach the correct answer. A system or a set of processes that supports such maintenance of task-relevant information during the performance of a cognitive task is called *working memory.* As reflected by the fact that it has been considered the mind's work space, working memory is a central construct in cognitive psychology and cognitive neuroscience.

The notion of working memory evolved from an earlier conception of short-term memory. Like working memory, short-term memory is a system for enabling temporary maintenance of information, but its maintenance functions are primarily for the sake of memorization (e.g., remembering an unfamiliar phone number until it is dialed) and are far removed from other cognitive processes that support active thinking. In contrast, the central idea behind working memory is that its maintenance functions are in the service of complex cognition and fundamentally support performance of complex cognitive tasks. In other words, the memory part of working memory is not passive and static, but active and working, as its name indicates.

A Multicomponent View of Working Memory

There are a number of well-developed models and theories of working memory (for an overview, see Miyake & Shah, 1999), but the best known model is the multicomponent model developed by Alan Baddeley (1986). According to this model, working memory is a system that consists of three major subsystems. Two of the subsystems, called the phonological (or articulatory) loop and the visuospatial sketchpad, are specialized slave systems whose primary functions are the temporary maintenance and processing of speech-based phonological information and of visual and spatial information, respectively. Each subsystem is assumed to consist of two separable components, a passive phonological store and an active rehearsal process for the phonological loop (Baddeley, 1986) and a visual component (visual cache) and a spatial component (inner scribe) for the visuospatial sketchpad (Logie, 1995). The remaining subsystem is called the central executive and is a general-purpose control structure that regulates the operations of the two slave systems and modulates the flow of information within working memory.

The tripartite structure of Baddeley's (1986) model has been supported by various sources of evidence, particularly with respect to the separability of the two slave systems. For example, secondary tasks that tap the phonological loop's functions, such as repeating a familiar phrase over and over (called articulatory suppression), impair the maintenance of phonological information but not visuospatial information (Baddeley, 1986), whereas secondary tasks that tap the visuospatial sketchpad's functions, such as viewing dynamic visual noise (called the irrelevant picture paradigm), impair the maintenance of some types of visual information but not verbal information (Quinn & McConnell, 1996). In addition, individuals with brain damage have demonstrated selective impairments in the phonological loop or the visuospatial sketchpad (Gathercole, 1994). More recently, neuroimaging studies have produced evidence suggesting that different neural circuits may mediate the maintenance of phonological and visuospatial information (Smith & Jonides, 1999).

Within the framework of this multicomponent model, the main focus of current research is to specify the organization and functions of the central executive, the least understood subsystem of working memory. Although it has been criticized as a homunculus or a theoretical ragbag, interest in understanding this crucial component has been rising (Miyake & Shah, 1999). In particular, researchers have started to specify the subcomponents or subfunctions of the central executive (Baddeley, 1996), as well as the role of the prefrontal cortex in the executive control of behavior (Smith & Jonides, 1999).

More recently, Baddeley (2000) proposed a possible fourth subcomponent of working memory, called the episodic buffer. This buffer is thought to be responsible for integrating or binding multiple sources of information derived from different memory systems (e.g., binding items in the phonological loop with relevant pieces of information in long-term knowledge) and temporarily maintaining the resulting multimodal representations within working memory. Although this new concept helps resolve some difficulties that the original tripartite version of the model had faced, it remains to be seen whether the episodic buffer will become as widely accepted as the other subsystems.

Measurement of Working Memory and Its Role in Complex Cognition

The capacity of short-term memory has traditionally been assessed with a simple span task that requires participants

to repeat back a list of digits or words in correct sequence. In contrast to such storage-oriented measures, currently used measures of working memory capacity require participants to perform a dual task, namely the simultaneous processing of some information and remembering of to-be-recalled items. The best-known measure of this kind is the reading span test (Daneman & Carpenter, 1980), in which participants read sentences aloud while remembering the final word of each sentence for later recall. Performance on this task has been shown to correlate well with complex cognitive tasks, such as reading comprehension. According to a meta-analysis (Daneman & Merikle, 1996), the average correlation between the reading span score and global comprehension measures like the Nelson-Denny Reading Test was .41 and was significantly higher than that between traditional short-term memory measures and comprehension measures (.28 for word span and .14 for digit span). Following this success, a number of variants have been developed, including the operation span, counting span, and spatial span tests (Engle, Tuholski, Laughlin, & Conway, 1999; Shah & Miyake, 1996).

These complex span tasks have served as useful research tools to examine the role of working memory in various complex cognitive tasks. Tasks examined in some depth include language comprehension, language learning, spatial thinking, retrieval from memory, and problem solving and reasoning (see Miyake & Shah, 1999, for some illustrative examples of this line of research). Although the extent to which the capacities measured by the complex span tasks is domain-specific or domain-general is under debate, the proposal that working memory capacity may be a key component of general fluid intelligence (Engle et al., 1999) further underscores the importance of working memory in complex cognition.

ZEIGARNIK EFFECT

Work by Bluma Zeigarnik (1927) established the fact that subjects ranging widely in age tended to remember interrupted tasks better (and with greater frequency) than they did tasks they had completed.

What amounted to common-sense observation constituted the impetus for a series of germinal experiments by Zeigarnik. In a typical study, subjects were asked to perform a series of different tasks, ranging from 15 to 22 in number. Some tasks were of a manipulatory nature (such as stringing beads); others clearly involved the application of mental ability (such as puzzles). For half of the activities, subjects were allowed to continue until they were finished. In the case of a puzzle, for example, work might proceed until a solution was found. In the remainder of the activities (one half of the total), the experimenter asked subjects to stop working on a given task and to move on to something else. Following the activity or task session, the tasks were removed from the subjects' view, and each was asked to recall and to jot down some of the activities in which they had been involved. Most subjects were able to recall a number of tasks immediately but required some deliberation time to recall others. Results of the study confirmed Zeigarnik's initial hypothesis. The number of unfinished or incompleted tasks (designated *I*) that were recalled was significantly higher than was the number of completed tasks (designated *C*). By and large, subjects taking part in Zeigarnik's research were twice as likely to recall incompleted tasks as completed ones.

In the series of Zeigarnik studies, the recall ratio for tasks interrupted at the middle or toward the end (tasks nearing completion) was higher than for tasks interrupted at or near the beginning of work on them. This finding attested to the increasing involvement of a subject in moving a given task along to completion. The *I/C* ratio was seen to increase as the subject moved nearer and nearer to the goal of a satisfactory task solution.

During the course of her research, Zeigarnik discovered that persons who could be easily classified as being ambitious (high achiever) had a higher *I/C* ratio than did persons of average ambition. Ambitious (high achiever) subjects forgot completed tasks at a faster rate than did those of average ambitiousness. If task interpretation were to be interpreted by subjects as signifying that they had failed, generating an ego-threatening situation, the *I/C* ratio would be further increased, with subjects tending to recall incompleted tasks with greater frequency than before.

Studies have found that the Zeigarnik effect is sensitive to a number of factors that may be difficult, if not impossible, to control within the context of a laboratory study: (1) The Zeigarnik effect is less likely to appear if the subject is, to some extent, ego-involved in the task; (2) the effect is more likely to appear if the interruption of the task does not seem to be part of the experimental game plan; and (3) the effect is most likely to appear if the subject has set a genuine level of aspiration in the interrupted task, that is, has not come to the conclusion that the thing is impossible or beyond his or her capacity.

ZEITGEBERS

Physiological functions such as temperature, blood pressure, blood nutrients and hormones, and sleep-wake cycles fluctuate in a rhythmic pattern the period of which is 24 hours. Such fluctuations are called circadian rhythms, meaning "about a day." The cycle length or period of circadian rhythms under constant, aperiodic conditions, such as constant light or constant darkness, typically deviates from a 24-hour period. Under these conditions circadian rhythms are said to be free running because they no longer are entrained or synchronized by exogenous factors to a constant period in relation to the environment. When the young adult circadian system runs free, its periodicity is typically closer to 25 hours than 24 hours. This is due to certain critical exogenous factors that can synchronize circadian rhythms into stable period and phase relationships with the external day-night cycle. These exogenous factors are termed *zeitgebers* (time keepers) and include both phys-

ical and social factors (Aschoff, Hoffman, Pohl, & Wever, 1975).

How Zeitgebers Entrain Circadian Rhythms

In many animals, light is the primary zeitgeber that entrains circadian cycles (Aschoff, 1981; Pittendrigh, 1981). The brain pathway by which light entrains circadian rhythms has been clearly elucidated in animal studies (Moore & Eichler, 1972). This neuronal circuit involves ocular mechanisms (Reme, Wirz-Justice, & Terman, 1991) and a projection from the retina directly to a nucleus in the base of the brain called the suprachiasmatic nucleus (SCN; Moore & Lenn 1972). The suprachiasmatic nucleus has been called the body's biological clock (Rusak, 1989; Rusak & Haddad, 1993; Rusak & Zucker, 1979).

Photic and Nonphotic Zeitgebers

It appears that nonphotic factors such as social factors or social rhythms may also be important in the setting of circadian rhythms in human subjects (Aschoff, Fatranska, & Giedke, 1971; Mrosovsky, 1996; Wever, 1975, 1979, 1988). As well as acting as a direct zeitgeber, social rhythms can indirectly determine when a person is exposed to physical zeitgebers such as daylight and darkness. Moreover, social rhythms also determine when a person goes to bed or gets up and thus set the timing of their sleep-wake cycles. Social entrainment begins soon after birth so that an offspring's eating and sleeping schedules become synchronized with those of siblings and parents.

Social rhythms are maintained by a variety of factors such as occupation, marital status, presence or absence of children, and recreational activities. Thus, interruption of these factors has the potential for disruption of normal circadian timing. The mechanism by which social rhythms participate in entrainment of biological rhythms is unknown. Some authors have suggested, based on animal studies, that social interactions or behavioral activity might cause a nonspecific increase in arousal, which could then feedback on the pacemaker in the SCN (Mrosovsky, Reebs, Honrado, & Salmon, 1989; Turek & Losee-Olsen, 1986; Van Reeth & Turek, 1989). Recently, Moore and Card (1990) proposed that social Zeitgebers may entrain the SCN through a specific neuropeptide Y pathway that involves the intergeniculate leaflet. It has also been suggested that nonphotically entrainable oscillators may exist outside the SCN (Mikkelsen, Vrand, & Mrosovsky, 1998; Mistlberger, 1992).

Consequences of Disruptions of Zeitgebers

A loss or disruption of a zeitgeber can have important consequences on physiological and psychological functioning. Transmeridian flight has been demonstrated to be a potent source of rhythm disruption (jet lag). When a person takes a transmeridian flight, he or she will be exposed to new physical and social time cues (zeitgebers). Shift work represents another case of rhythm disturbance. It is perhaps not surprising that in addition to the jet lag-like symptoms of sleep disruption, malaise, and gastrointestinal disorders (Rutenfranz, Colquhoun, Knauth, & Ghauta, 1977), shift work has been found to be associated with increases in divorce (Knutsson, Akerstedt, Jonsson, & Orth-Gome, 1986; Tepas & Monk, 1987), increased risk of heart disease (Knutsson et al., 1986), difficulty concentrating and irritability (Rutenfranz et al., 1977), and heavier use of caffeine and alcohol (Gordon, Cleary, Parlan, & Czeisler, 1986; Monk, 1988; Regestein & Monk, 1991).

Zeitgebers and Depression

Photic Zeitgebers

Several recent theories have focused on changes in zeitgebers as an etiology of depression. The effect of physical zeitgebers on the development of depressive symptoms has been stressed by researchers who have studied seasonal affective disorder (SAD; Lewy, Sack, & Singer, 1984; Rosenthal et al., 1984). The classic presentation of SAD is the occurrence of depressive symptoms that begin late in autumn and resolve in spring. One treatment used for SAD is bright light exposure in early morning and/or late afternoon in order to approximate the daylight levels of a summer day (see Lewy et al., 1980; Kripke, 1982). Some patients with SAD do obtain relief from depressive symptoms using bright light exposure.

Nonphotic Zeitgebers

Although many studies suggest that light may play a role in the etiology and treatment of seasonal depressive disorders, studies in nonseasonal depression have not demonstrated any consistent therapeutic effect of bright light. Some theories have stressed the role of social zeitgebers in the onset and course of affective illness. In one model, certain life events and difficulties (Brown & Harris, 1986; Brown, Harris, & Peter, 1973), particularly those that involve separation or loss such as death, divorce, loss of job, moving, and so on are viewed as a loss of social zeitgebers. A loss of social zeitgebers, in turn, is postulated to produce changes in social rhythms, or the rhythmicity of the activities of daily life. Disruption in social rhythms are then thought to lead to changes in biological rhythms. Ultimately, it is postulated that chronic disruption of social and biological rhythms can lead to the onset, in vulnerable individuals, of depression. Whether a person actually becomes ill following the loss of a social zeitgeber is thought to depend on certain vulnerability factors such as genetic-familial loading, social supports, past history of affective episodes, and personality variables (Ehlers, Frank, & Kupfer, 1988; Ehlers, Kupfer, Frank, & Monk, 1994; Frank et al., 1994; Healy & Waterhouse, 1995).

Z-PROCESS

The Z-process is a psychotherapeutic and attachment system, incorporating ethological and attachment principles, developed to overcome resistance to human bonding and growth. The autistic child shows self-destructive aggression and does not direct aggression toward other people. The Z-process treatment of autistic children led to the conclusion that such psychopathology results from a failure to develop two bonding behavior networks essential for the growth of viable attachment: (1) body contact, necessary for intimacy and basic trust; and (2) eye-face contact, necessary for the direction, integration, and focus of complex emotional and cognitive social behavior. A disturbance in these bonds is called the *Medusa complex,* which is corrected by holding the child in "protest" while maintaining eye-face contact. Niko Tinbergen and his collaborators have reported significant success in using the holding approach with autistic children.

Z-SCORE

The z-score, also known as the standard score, is the result of a transformation of raw data, and this conversion can be summed up as follows: Something minus its mean divided by its standard deviation. The "something" in this statement is usually one of two things: a raw data point within a set of observations or the observed mean of a sample of data. When such a transformation is applied to all observations within a data set, the first step of subtracting the mean from each individual observation has the effect of re-centering the distribution at a mean of zero. Because dividing all observations within a data set by a constant results in the standard deviation of the distribution being similarly reduced by that factor, the second step in the transformation results in a standard deviation of one for the distribution of z-scores. Thus, when a distribution of scores is converted to z-scores, the resulting distribution is centered at a mean of zero with a standard deviation of one. In addition, a distribution of z-scores retains the shape of its parent distribution. It follows from this attribute that when the parent distribution is normally distributed, so too will be the corresponding z-score distribution. When the size of the sample gets very large, this normal distribution of z-scores is given a special name, the standard normal distribution (see Figure 1), which is discussed in more detail later.

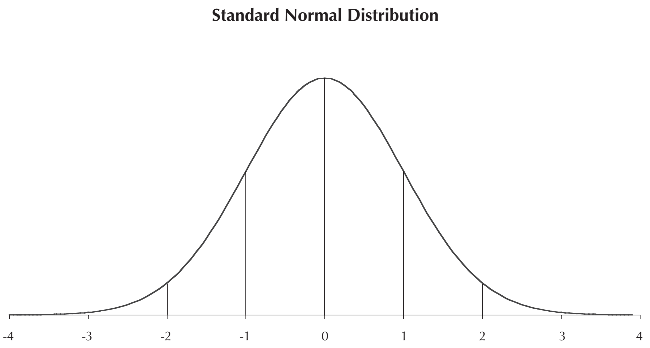

Figure 1. *Z*-scores.

The *Z*-Score as a Descriptive Statistic

A z-score for something indicates its location in relation to the mean of the distribution from which it was drawn. Specifically, a z-score is interpreted as how many standard deviations a score is above (positive z-score) or below (negative z-score) its mean. Returning to our general definition of a z-score as "something minus its mean divided by its standard deviation," we arrive at the following formula for converting an observation from a sample to a z-score:

$$z = (x - \bar{x})/s$$

in which $\bar{x}$ is the sample mean from which x is drawn and s is the standard deviation. To illustrate with an example, suppose that in a sample of adult males, the average weight is 185 lb, and the standard deviation is 15 lb. The z-score for an observation of 170 lb would be (170 – 185)/15 = –1.0. Therefore, we know that a man weighing 170 lb in this sample is 1.0 standard deviation below the mean. A z-score thus conveys the following information about its corresponding raw score: (1) how many standard deviations away from the mean of the distribution the score is, indicated by the absolute value of the score, and (2) whether the score falls above or below the mean of the sample, indicated by the sign of the score (see Figure 1). All z-scores, whether resulting from the transformation of raw data points or means of samples, are interpreted in this way.

The use of z-scores instead of raw sample data or even other measures of relative standing is preferable for several reasons. First, because the unit of measurement for z-scores is standard deviations in relation to the mean of a group of data, observations from different samples or populations can be compared directly with a common metric. Second, although other indexes of relative standing exist (e.g., percentile rank), not all preserve a 1:1 relationship with the parent distribution as the z-score does. For instance, a move from the 80th to 89th percentile (a difference of 9 percentile units) might represent a change of 10 units in the distribution of raw data, whereas a move from the 90th to 99th percentile (still a difference of 9 percentile

units) might represent a change of 15 units in the raw data. On the other hand, a particular difference between z-scores, regardless of which two z-scores are examined to produce that difference, will always represent the same discrepancy between the corresponding raw scores in the parent distribution.

The *Z*-Score as an Inferential Statistic

When used as an inferential statistic, the z-score is not calculated from a particular data point within a sample, but rather from a sample mean. When a study sample is selected, it is basically drawn from a distribution of samples; thus, individual cases are not being sampled, but rather a particular mean. When the observed mean of a sample is converted to a z-score, we are thus calculating how deviant this study mean is from the mean of its hypothetical distribution, which is composed of all possible means that could be observed with samples of the same size. The definition of a z-score, "something minus its mean divided by its standard deviation," when the "something" is a sample mean, is given by the formula

$$z = \bar{x} - \mu/(\sigma/\sqrt{n})$$

Here, $\bar{x}$ is the sample mean being transformed. Again, because $\bar{x}$ is a sample mean, it was drawn from a distribution of sample means of a particular variable. According to the central limit theorem, as sample sizes get larger, this sampling distribution of means will approximate a normal distribution with a mean of μ and a standard deviation of $\sigma/\sqrt{n}$. Here, μ is the population mean for variable x, σ is the population standard deviation, and n is the size of the samples composing the sampling distribution for variable x.

The fact that the sampling distribution of means for a variable will always be normal with samples of sufficient size is not trivial and is in fact central to the utility of the z-score as an inferential statistic. Recall that a distribution of z-scores will retain the shape of its parent distribution. Because the sampling distribution of means is normal, so too will be the corresponding z-score distribution, the standard normal distribution. A z-score table has been derived for this distribution, detailing the proportion of cases that are more extreme (i.e., are further from the mean) than any given z-score (see Table 1). Basically, the standard normal distribution can be thought of as a pie, with an area of 1.0; when we cut this pie at a particular z-score value, we can determine what area of the pie lies on either side of the cut. Areas under the curve associated with particular z-scores are found in the z table and are shown pictorially in Figure 2. The key is that these areas reflect probabilities associated with the corresponding z-scores. Thus, if we look at Figure 2, we see that the proportion of the curve lying beyond a z-score of +1.0 is approximately .16. Because the standard normal distribution is normal, and thus symmetrical, a z-score of –1.0 also cuts off a proportion of .16 in the lower tail. Another way to say this is that the probability of selecting a z-score of 1.0 or greater from the standard normal distribution is .16, or that approximately 16% of observations in a normally distributed population will be greater than an observation producing a z-score of 1.0. Notice that the information in Figure 2 corresponds to proportions that can be found in the z table: Looking under the z-score column, we see that the area beyond a z-score of 1.0 is .1587. If we were not dealing with a normal distribution, we could not compare our calculated z-scores to this table of proportions to determine how extreme (i.e., improbable) a given z-score is, greatly limiting our inferential abilities. How this table is used for inferential purposes is discussed next.

Table 1. Selected Values of z From the z Table.

z	Area beyond z
0.0	.5000
0.33	.3707
0.5	.3085
1.0	.1587
1.5	.0668
2.0	.0228
2.5	.0062
3.0	.0014

Note: Proportions of total are under the normal curve.

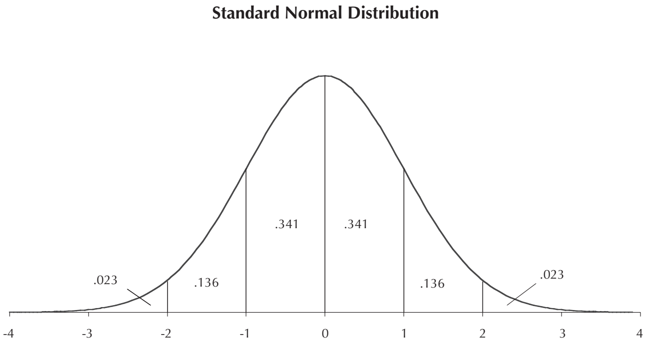

Figure 2. *Z*-scores and corresponding areas under the normal curve.

Because it is only hypothesized that a study sample is drawn from a particular population of given μ and σ, we can test our assumption by computing a z-score for the observed sample mean in order to determine if it is significantly different from the population mean (recall that this is also the mean of the sampling distribution of means for that variable). If the sample mean differs greatly from the population mean (i.e., produces a large z-score), then it might be concluded that the study sample was drawn from another sampling distribution with a more similar mean. But how do we determine if our sample mean is significantly different from the population mean? How improbable would a z-score and its corresponding sample mean have to be within

a particular sampling distribution of means to decide that it is probably not drawn from that population? After all, just because an event is improbable does not mean that it is impossible. In psychology, the convention is to conclude that a *z*-score is significant (i.e., significantly different from the population mean to which it is being compared) if the probability of observing such a *z*-score is .05 or less. To return to our pie analogy, this means that the observed *z*-score cuts off a total of 1/20 of the pie in either one or both tails, depending on the hypothesis (i.e., a proportion of .05). In such a case, the null hypothesis that states that the sample mean equals the population mean for a given variable is rejected. The implication is that the study sample appears to have been drawn from a population distinct from that to which it was compared, a population with a mean more similar to its own. Fortunately, this test of significance is quite simple, as we can use the *z*-score table to determine the probability of obtaining any *z*-score.

Let's return to our weight example to illustrate. Assume that we want to test whether our group of adult men discussed earlier—say there are 25 of them—has been drawn from a population in which the mean is known to be 200 lb and the standard deviation is 25 lb. Because we calculated that the mean of our sample is 185 lb, the corresponding *z*-score is $(185 - 200)/(25/\sqrt{25}) = -.33$. Going to the *z* table, we see that the probability of obtaining a *z*-score of –.33 is .3707, well above .05. Thus, we conclude that observing a mean of 185 lb in a sample of 25 adult men is not so improbable given a population of the parameters mentioned. Thus, we would not determine that our sample mean is statistically different from the given population mean, and thus probably does not represent a different sampling distribution.

Joshua W. Madsen
University of Colorado at Boulder

BIOGRAPHIES

ABELES, NORMAN (b. 1928) Abeles is best known for his research on the interaction between mood and memory in older adults. He established the Clinical Neuropsychological Laboratory at Michigan State University. He has been president of the American Psychological Association and is very involved in its government.

ADLER, ALFRED (1870–1937) Adler founded the school of Individual Psychology. He saw the individual in its unity and goal orientation operating as if according to a self-created life plan, later called *lifestyle.* Drives, feelings, emotions, memory, the unconscious, and all processes are subordinated to the lifestyle.

AINSWORTH, MARY D. S. (1913–1999) Ainsworth devoted a lifetime to researching infant-mother relationships and introduced a 20-minute controlled laboratory technique called the *strange situation.* She extended her research into attachment beyond infancy by examining other affectional bonds throughout the life cycle.

AKIL, HUDA Akil's research primarily focuses on the brain biology of stress and depression and on the biology of endorphins and other molecules related to substance abuse. Her research takes a broad-based approach, examining the system at a cellular, molecular, and integrative level.

ALBEE, GEORGE (b. 1921) Albee's research focused on the prevention of psychopathology. He established the Vermont Conference on the Primary Prevention of Psychopathology and played a constructive role in defining the importance of prevention of disorders.

ALLPORT, FLOYD HENRY (1890–1978) Allport is considered to be the father of social psychology. In his theories and research he set a direction in social psychology that was followed by psychologists in that area for several decades.

ALLPORT, GORDON WILLARD (1897–1967) Allport regarded personality as the natural subject matter of psychology. His approach was eclectic, drawing on a wide variety of sources.

ALMEIDA, EDUARDO (b. 1937) Almeida conducted a program for the development of competence in school children from Mexico City. He also developed an instrument for studying public opinion.

AMES, LOUISE B. (1908–1996) Ames's books have been standard references on the developmental processes for both psychologists and parents.

ANASTASI, ANNE (1908–2001) Anastasi is most closely associated with the development of differential psychology. Her research centered chiefly on factor analysis, problems of test construction, and the interpretation of test scores.

ANGELL, FRANK (1857–1939) Angell established a laboratory at Stanford University. His research centered on psychophysics, especially auditory sensation.

ANGELL, JAMES ROLLAND (1867–1949) Angell stated that functional psychology was the study of mental operations, that psychology should be considered a study of the functional utilities of consciousness, and that psychology is concerned with the relationship between the body and the environment.

ANGYAL, ANDRAS (1902–1960) Angyal asserted that there are two basic patterns of motivation: striving toward mastery and striving toward love.

ANSBACHER, HEINZ L. (b. 1904) Ansbacher is the prime interpreter of Alfred Adler. His most important contribution is his clarification of Adler's concepts of lifestyle and social interest.

ANZIEU, DIDIER (b. 1923) Anzieu's main psychological concepts are *group delusion, skin ego, paradoxical transference,* and *creative psychological work.*

ARISTOTLE (384–322 B.C.) A student in Plato's Academy in Athens, Aristotle created a new science of logic, the art and method of correct thinking. He used his concepts—form, matter, substance, cause, potentiality, actuality, and substratum—as tools for problem solving. In Aristotelian thought, knowledge is expanded to include two classifications: theoretical science and practical science.

ASCH, SOLOMON (1907–1996) Asch is best known for performing a series of experiments to determine the effects of social pressures on single individuals.

ASTON-JONES, GARY Aston-Jones's major research interest is the role of brainstem neuromodulatory systems in attention, affect, and motivation. These interests have led him to focus on monoamine neurons that project to the

forebrain, especially with regard to their role in mental functions and dysfunctions.

ATKINSON, RICHARD C. Atkinson's research has dealt with problems of memory and cognition. He is best known for the Atkinson-Shiffrin model, a theory of memory that has helped in clarifying the relationship between brain structures and psychological phenomena.

AUSTAD, CAROL DONNA SHAW (b. 1946) Austad conducted research on the practice of psychotherapy in the managed-care setting.

AVENERIUS, RICHARD (1843–1896) Avenerius hypothesized that there was a system "C" on which consciousness depended. The significance of this concept lies in its influence on Titchener.

AXELROD, JULIUS (1912–1983) Axelrod discovered much of what we know about norepinephrine, serotonin, and dopamine, including their metabolic fates. He discovered the uptake sites for monoamines that represent the basis for the mechanism of action of the serotonin reuptake inhibitors as antidepressants.

AZUMA, HIROSHI (b. 1926) Azuma's work centers on the cognitive development of children, concept learning, and methods of instruction.

BACON, SIR FRANCIS (1561–1636) Bacon stated that in science there are two kinds of experiments: those that shed light and those that bring fruit. He was the first to call a halt to medieval speculation and superstition.

BADDELEY, ALAN (b. 1934) Baddeley demonstrated that long-term memory tends to rely heavily on meaning, as opposed to short-term memory, which relies more heavily on sound or speech coding.

BAIN, ALEXANDER (1818–1903) Bain stressed two basic laws of association: similarity and contiguity. He believed that sensations and feelings come together in close succession and in such a way that, when one of them is brought to mind, the other will most likely occur.

BAIRD, JOHN WALLACE (1873–1919) Baird was regarded as Titchener's most representative follower. He made systematic experimental introspection of the higher mental processes the central research topic of Clark University.

BAKARE, CHRISTOPHER G. M. (b. 1935) Bakare devised a statistical technique for identifying the "kernel of truth" in interethnic stereotypes to understand the conflicts that plague Africa's development.

BALDWIN, JAMES MARK (1861–1934) Known as a founding father of developmental psychology, Baldwin developed a thoroughgoing Darwinian genetic psychology. He stressed intentional action as the instrument of selection in mental development.

BALTES, PAUL B. (b. 1939) Baltes, a pioneer of life-span developmental psychology, emphasizes that individuals continue to maintain a capacity for change across the entire life span.

BANDURA, ALBERT (b. 1925) Bandura assigns a central role to cognitive, vicarious, self-regulative, and self-reflective processes in human coping and adaptation.

BARBER, THEODORE X. (b. 1927) Barber, a distinguished hypnosis researcher and theoretician, delineated three paradigms of responsive hypnotic subjects: positively set, fantasy-prone, and amnesia-prone hypnotic virtuoso.

BARKER, ROGER G. (1903–1990) Barker helped establish the Midwest Psychological Field Station, a pioneering center for research in environmental psychology that investigates relationships between environment and behavior.

BARLOW, DAVID H. (b. 1942) Barlow's work is in the areas of anxiety disorders, sexual problems, and clinical research methodology. His research continues to focus on developing new treatments for childhood anxiety disorders and exploring early psychological and social factors that create vulnerabilities for the development of anxiety disorders.

BARTLETT, FREDERIC C. (1886–1979) Bartlett is best remembered for his outstanding achievement in directing research regarding memory. His work is best represented by his classic book, *Remembering*.

BASOV, MIKHAIL YAKOVIEVICH (1892–1931) Basov was a Soviet psychologist who opposed a mechanistic point of view. He believed that heredity and environment both contributed to human growth and development, their roles changing from one phase of development to another.

BATESON, GREGORY (1904–1980) Bateson conducted anthropological research with the Baining and the Sulka of the Gazelle Peninsula and with the Iatmul of New Guinea. Later in life he explored the causes of maladjustments and mental disorders.

BATESON, WILLIAM (1861–1926) Bateson is best known for his contributions to the establishment of the Mendelian concept of heredity. Bateson named the new science "genetics" and extended his efforts to a study of chromosomes and genes.

BAYÉS, RAMÓN (b. 1930) Bayés is one of the founders of diverse entities in Spain, such as the introduction of behavior modification. He wrote the first Spanish book on behavioral pharmacology.

BAYLEY, NANCY (1899–1994) Among Bayley's seminal studies are longitudinal research on the life span; techniques for measuring behavioral, motor, and physical

development; and assessment of interactions between behavioral and biological development.

BEACH, FRANK A. (1911–1988) Known for his work in human and animal sexual behavior, Beach published his findings in *Patterns of Sexual Behavior.* In this book, sex is reviewed from cultural and evolutionary perspectives.

BECK, AARON T. (b. 1921) Beck developed his cognitive theory and therapy of psychopathology in the 1960s and 1970s. The various inventories he developed to test his new theory are among the most widely used psychological instruments.

BEEBE-CENTER, JOHN G. (1897–1958) Beebe-Center was an investigator of hedonic aspects. As a result of his studies of taste thresholds and the scaling of taste values, he developed a psychological scale of taste named the *gust scale*.

BEERS, CLIFFORD W. (1876–1943) Beers developed manic-depressive disorder and for 3 years was a patient in several hospitals. Following his recovery, he organized the first Society for Mental Hygiene in 1908. He authored the classic book *The Snakepit.*

BÉKÉSY, GEORG VON (1899–1972) Békésy is best known for his work in audition. He devised many new tools, such as the Békésy audiometer for measuring loss of hearing.

BÉKHTEREV, VLADIMIR M. (1857–1927) Békhterev is best known for his work on associated reflexes (usually referred to by Ivan Pavlov's term *conditioned reflexes*).

BELL, SIR CHARLES (1774–1842) Bell is known for his discovery that the sensory fibers of a mixed nerve enter the spinal cord at the dorsal root, whereas the motor fibers of the same nerve leave the cord by a ventral root.

BENEDICT, RUTH F. (1887–1948) Most of Benedict's research dealt with the origins of Native American cultures. She saw in each culture an assemblage of elements from many other cultures.

BENTON, ARTHUR L. (b. 1909) Benton's teaching and research career covered a variety of aspects of clinical neuropsychology, including hemispheric cerebral dominance, brain injury in childhood, aphasia, perceptual disabilities, and the development of neuropsychological assessment procedures.

BERNE, ERIC L. (1910–1970) Berne was the founder of transactional analysis, a system of group therapy that takes its name from analyzing interactions between individuals in terms of three ego states in each of us: the child, the parent, and the adult.

BETTELHEIM, BRUNO (1903–1990) Bettelheim was concerned with autistic and psychotic children. His theories tended to be psychoanalytic in opposition to the more biological approaches to childhood psychoses. He is well known for the case of "Joey, the Mechanical Boy."

BIEDERMAN, JOSEPH (b. 1947) Biederman has been concerned with the genetics and development of ADHD. He has made significant contributions to the understanding of the relationship of ADHD to comorbid disorders, especially bipolar disorders.

BIJOU, SIDNEY W. (b. 1908) Bijou was the director of the Child Research Laboratory and the Institute of Research in Exceptional Children at Champaign-Urbana Illinois, and the founding editor of the *Journal of Experimental Child Psychology.* With Donald Baer, he coauthored three influential books regarding human development from a behavioral perspective.

BINET, ALFRED (1857–1911) Binet acquired much of his data on intelligence by studying his daughters. He developed a test that became the first scale for the measurement of intelligence. This test was modified by Terman at Stanford University and became the Stanford-Binet Intelligence Test.

BINGHAM, WALTER V. (1880–1952) During World War I, Bingham served as executive secretary of the committee on classification of personnel in the U.S. Army. He was one of a small group that developed intelligence testing for the Army.

BLAKE, ROBERT R. (b. 1918) Blake has provided insight into group and intergroup dynamics, concentrating particularly on the organizational impact of group norms and the resolution of intergroup conflict.

BLAU, THEODORE H. (1928–2003) Blau has performed research on the nature and effects of mixed cerebral dominance. He proposed a neuropsychological/social influence theory of Schizophrenia as well as producing work on community interventions.

BLEULER, EUGEN (1857–1939) Bleuler introduced concepts such as neologism, word salad, and negative speech into the descriptive vocabulary of Schizophrenia, as well as the notions of autism and ambivalence.

BLOOM, BERNARD (b. 1923) Bloom established the nationally recognized doctoral program in community/clinical psychology at the University of Colorado at Boulder. His major work was on very short-term therapy.

BOAS, FRANZ (1858–1942) Boas wanted to make anthropology a rigorous and exact science. In many of his investigations he noted parallel developments in widely separated areas.

BODER, DAVID PABLO (1886–1961) After the Russian Revolution, Boder traveled to Mexico, where he was placed in charge of psychological research in penal institutions. Later, he established a psychological museum in the United States.

BOLLES, ROBERT C. (b. 1928) Bolles's research ranged over different areas of animal motivation and later focused on avoidance behavior. He developed the concept of species-specific defense reactions.

BONNET, CHARLES (1720–1793) Bonnet and Condillac used the analogy of a human as a statue. Condillac had avoided physiology, but Bonnet wrote of nervous fluids and agitation of the nerve fibers. He may have anticipated the doctrine of the "specific energies of nerves."

BORGATTA, EDGAR F. (b. 1924) Borgatta's early research focused on role-playing techniques and sociometric analysis. Later, his research addressed the formal properties of small groups and the structure of interaction processes, as well as scaling and statistical analysis.

BORING, EDWARD G. (1886–1968) Boring's *History of Experimental Psychology* is a widely accepted classic. It brought together the creative scientist and the *Zeitgeist,* or spirit of the times, and explained how their interaction affected the direction of psychology.

BORKOVEC, THOMAS D. (b. 1944) Borkovec has focused on theories of anxiety development and the treatment of Generalized Anxiety Disorders.

BOUCHARD, JR., THOMAS J. (b. 1937) Bouchard's career has primarily focused on human individual differences. His major contribution has been estimating the various types of environmental and genetic influences on human psychological and medical/physical characteristics.

BOWDITCH, HENRY PICKERING (1840–1911) Bowditch was the first to demonstrate the all-or-nothing law of nerve transmission in heart muscle fibers. The principle that nerves cannot be fatigued is known as Bowditch's law.

BOWER, GORDON HOWARD (b. 1932) Bower's early research involved operant conditioning with lower animals. His interests then turned to problems in human learning, including mathematical models of learning. Bower played a major role in the development of cognitive psychology.

BOWLBY, JOHN (1907–1990) Bowlby is known for his work on the ill effects of maternal deprivation on personality development and for formulating attachment theory as a way of conceptualizing a child's tie to his or her mother.

BRADLEY, FRANCIS HERBERT (1846–1924) Bradley emphasized the importance of individuals to find themselves first as a whole and then bring themselves into line with the world of completely harmonized experience with an infinite coherent unity.

BRAID, JAMES (ca. 1795–1860) Braid generally is credited as the discoverer of hypnosis, although the phenomenon had been known and practiced earlier by Mesmer, Elliotson, and Esdale. His significance is that he removed the phenomenon from the realm of mystical explanation.

BRAY, W. CHARLES II (1904–1982) Bray's research was mostly on hearing, especially on electrical potentials in the cochlea and auditory nerve action in response to sounds. His work initiated the field of auditory electrophysiology.

BRENMAN-GIBSON, MARGARET (b. 1918) Best known for her work on altered states of consciousness and their uses in psychoanalytic psychotherapy, Brenman-Gibson has extended this interest to the creative state in writers.

BRENTANO, FRANZ (1838–1917) Brentano, in opposition to Wilhelm Wundt's views, proclaimed that the primary method of psychology was observation—not experimentation. He differentiated the act of seeing color from the sensory content of color.

BRETT, GEORGE S. (1879–1944) Brett is primarily known for his monumental three-volume work, *A History of Psychology.* He traced psychology from its earliest beginnings in ancient Greece to the twentieth century.

BREUER, JOSEPH (1842–1905) Prior to his first encounters with Freud, Breuer had been treating a young woman known as Anna O. Along with hypnosis, he had been using the talking-out method in treating her symptoms. He discovered that, if placed under hypnosis and encouraged to talk out her feelings and recall her past experiences, she felt better after being removed from the hypnotic state. Breuer worked in collaboration with Freud in Vienna.

BREZNITZ, SHLOMO (b. 1936) Breznitz discovered and documented the phenomenon of *incubation of threat,* whereby fear of danger grows with anticipation.

BRIDGMAN, PERCY W. (1882–1961) Seeking to clarify the nature of physical concepts, Bridgman introduced the notion of operational definition: A concept is to be defined in terms of the operations by which it is observed.

BROADBENT, DONALD E. (1926–1993) Primarily an occupational or "human factors" psychologist, Broadbent was probably best known for an early advocacy of information-processing models for memory in human beings.

BROCA, PAUL (1824–1880) Although later research indicated that speech is too complicated a mechanism to be confined to one specific area of the brain, Broca is best known today for this. This area of the brain became known as "Broca's area."

BRUCH, HILDE (1904–1984) Bruch's research focused on childhood obesity, anorexia nervosa, and the relationship of eating disorders to Schizophrenia development.

BUNNY, W. E. After a long stretch at NIMH, Bunny became chair of Psychiatry at the University of California, Irvine, and has made pioneering breakthroughs in research spanning from the biology of Schizophrenia to mood disorders.

BURT, CYRIL L. (1883–1971) Burt was a leading British psychologist, especially in the areas of child development and statistics. He is a pioneer in the development of child guidance clinics in England and developed techniques of factor analysis. The integrity of his research methods and data has been severely criticized.

BUTTERS, NELSON (1937–1995) Butters's major contribution was to theories and assessment of neuropsychology.

CALKINS, MARY (1863–1930) Calkins invented the method of paired associates for the study of memory.

CAMPBELL, DONALD T. (1916–1996) Campbell was best known for his methodological writings, of which "Convergent and Discriminant Validation by the Multitrait-Multimethod Matrix" (Campbell and Fiske), and *Experimental and Quasi-Experimental Designs for Research* (Campbell and Stanley) are the best known. Later in life, his writings focused on philosophy of science issues.

CANNON, WALTER B. (1871–1945) Cannon's research on emotion and its effect on digestive processes was especially important for the field of psychology. Further exploration in this area led him to discoveries of other adaptive changes in the physiology of the body under emotion and stress. A critique of William James's theory of emotion led to Cannon's substitute theory, now known as the Canon-Bard Theory of Emotion.

CATANIA, CHARLES (b. 1936) As a behavioral pharmacologist, Catania has written on topics in the experimental analysis of behavior, including learning, reinforcement schedules, and verbal behavior.

CATTELL, JAMES McKEEN (1860–1944) The theme of Cattell's research was individual differences. His work contributed to the practical and applied psychology that was functional and uniquely American.

CATTELL, RAYMOND B. (1905–1998) Cattell derived his distinction in psychology from multivariate factor analysis and from numerous tests measuring various aspects of personality and intelligence that he developed.

CHA, JAE-HO (b. 1934) Cha was responsible for identifying a class of social perceptual phenomena, including dissonance effect and perceptual constancies, that he named the *discounting effect.*

CHAPANIS, ALPHONSE (1917–2002) Sometimes called the father of human factors, or ergonomics, Chapanis acquired his taste for applied work while wrestling with the difficult problems encountered by the men who had to fly and fight in the military aircraft of World War II.

CHARCOT, JEAN-MARTIN (1825–1893) Charcot is best known for his studies on hypnosis and hysteria. He believed that hypnosis was a condition peculiar to hysterical patients and a useful method for investigating hysterical predispositions.

CHARNEY, DENNIS (b. 1951) Charney has worked primarily in biological bases and treatments of mood and anxiety disorders.

CHAVEZ, EZEQUIEL A. (1868–1946) Chavez was considered by James Mark Baldwin to be the pioneer of Mexican psychology. He promoted educational reform that permitted him to teach the first psychology course in Mexico.

CHELPANOV, GEORGII IVANOVICH (1862–1936) For Chelpanov, the brain was the seat of the soul, through which psychology could be expressed. The soul was distinct from matter, but through proper experimental techniques it could be studied and understood.

CHEN, LI (b. 1902) Chen's work, mostly in the area of industrial psychology, has made significant contributions to the development of modern Chinese psychology. His study on the differentiation and integration of the *g* factor was recognized as a landmark in understanding intellectual development.

CHILD, IRVIN L. (1915–2000) During the 20th century, Child was one of the prominent figures in child development. He was also concerned with major societal factors, such as poverty, that had an impact on development.

CHOI, DENNIS Choi has contributed importantly to current understanding of mechanisms responsible for neuronal cell death after acute central nervous system insults, including NMDA receptor-mediated excitotoxicity, excessive calcium or zinc influx, and programmed cell death.

CHOMSKY, A. NOAM (b. 1928) Chomsky views the understanding of language as genetically determined and developing comparably to other bodily organs. He argues that learning a language is both species-specific and species-uniform: Only humans have the capacity for language acquisition, and all languages share a common underlying logical structure.

CLARK, KENNETH B. (1914–2000) Clark's research on the effect of segregation on the personality development of children was influential in the U.S. Supreme Court's historic 1964 *Brown v. Board of Education of Topeka, Kansas* decision. Along with his wife, Dr. Mamie Phipps Clark, Clark worked tirelessly to increase the participation of low-income groups in decisions on education, housing, employment and training, and economic development.

COIE, JOHN D. (b. 1940) The primary focus of Coie's research has been the development and prevention of serious antisocial behavior. He theorized that person-based effects on the social environment mediate the overall development of psychopathology and violence.

CORNELIUS, HANS (1863–1910) Cornelius maintained that the form quality was an attribute of experience and must be perceived as a whole (not broken down into individual experiences), as Wundt had suggested.

CORSINI, RAYMOND J. (b. 1914) The original editor of the *Corsini Encyclopedia of Psychology and Behavioral Science,* Corsini is best known for his unique style of dealing with problems in counseling and psychotherapy.

COUÉ, EMILE (1857–1926) Coué, a chemist, studied hypnotism under Bernheim and Liébeault. He claimed that, by means of autosuggestion, ideas that caused illness might be suggested away. His statement, "Every day in every way I am becoming better and better," has become proverbial.

COYLE, JOSEPH T. (b. 1943) Coyle discovered the loss of cholinergic cells in Alzheimer's disease and invented the radioenzymatic assay for catecholamines that revolutionized the field. Most recently he has been working on the role of glutamate in the biology of Schizophrenia.

CRAIGHEAD, W. EDWARD (b. 1942) Craighead has worked on the relationship of cognitive dysfunction and depression. Most recently his work is on prevention of first episode and recurrence of depression among adolescents.

CRONBACH, LEE J. (1916–2001) Cronbach's research was concerned with new approaches to the validation of psychological tests. In education psychology, he has stressed the relationship between classroom practices and basic psychological principles, particularly those of generalization and the transfer of training.

DAHLSTROM, W. GRANT (b. 1922) Dahlstrom focused on the assessment of personality. He played a major role in the evaluation and development of the MMPI-II.

DARLEY, JOHN GORDON (1910–1990) Darley's publications were in the areas of vocational interest measurement, student performance in higher education, student counseling, individual differences, social psychology, and psychometric theory.

DARWIN, CHARLES (1809–1882) Darwin's work influenced psychology in many ways. It changed the goal of psychology to the study of the organism's adaptation to its environment and placed increasing emphasis on individual differences among members of the same species.

DAVIS, MICHAEL (b. 1942) Davis pioneered research on the neurobiology of emotion with an emphasis on the amygdala.

DAVISON, GERALD C. Davison's research focuses on the relationships between cognition and a variety of behavioral and emotional problems via his articulated thoughts in simulated situations. His book *Clinical Behavior Therapy* (coauthored with M. Goldfried) is regarded as one of the definitive texts on the ways theory and research in cognitive behavior therapy are translated into clinical application.

DENMARK, FLORENCE L. (b. 1936) A pioneer in the field of the psychology of women, Denmark's most significant research has emphasized women's leadership and leadership styles, the interaction of status and gender, women in cross-cultural perspective, and the contributions of women to psychology.

DESCARTES, RENÉ (1596–1650) Descartes is renowned as the father of modern philosophy. He emphasized the individual thinker: the question of what a particular person may know, rather than what people may know. A rationalist, he defined knowledge as judgments or statements that can be said to be certain or indubitable, and he denied that sense experience can lead to knowledge in this way.

DEUTSCH, MORTON (b. 1920) Under the influence of K. Lewin's dictum, Deutsch believed that there was nothing so practical as a good theory. His classic study on the effects of cooperation and competition was the taking-off point for much of his subsequent work, which helped to stimulate the development of a movement toward cooperative learning in schools.

DEWEY, JOHN (1859–1952) Dewey's paper "The Reflex Arc Concept in Psychology" is usually credited with establishing functionalism as a defined school of psychology, rather than just an orientation or attitude.

DINGLEDINE, RAYMOND (b. 1948) Dingledine's most significant research accomplishments are the discoveries that glycine is a coagonist of NMDA receptors; that the transition between interictal and ictalstates in the high potassium model of seizures involves shrinkage of extracellular space; that one amino acid residue controls calcium permeation in glutamate receptor channels; that the channel-lining domain of glutamate receptor subunits is a reentrant loop rather than a transmembrane domain; and that the potency of certain ifenprodil analogues as NMDA receptor antagonists is enhanced at ischemic pH.

DOLLARD, JOHN (1900–1980) Dollard's studies achieved a remarkable synthesis of psychoanalysis, experimental psychology of learning and motivation, sociological analysis of social structure, and anthropological awareness of cultural variation.

DONDERS, FRANS C. (1818–1889) Donders is most prominently known for his studies on reaction time.

There were appreciable individual differences among observers. The particular reaction time, as it differed from one astronomer to another, became known as the *personal equation.*

DOWNEY, JUNE ETTA (1875–1932) Downey was the first psychologist to study individual differences in temperament. She developed the Will Temperament Test.

DREIKURS, RUDOLF (1897–1972) Dreikurs, an Adlerian, pioneered group psychotherapy and developed the "double interview" in therapy. He was deeply concerned with social equality, which he viewed as the basis for mental health.

DUBOIS, PAUL-CHARLES (1848–1918) Dubois may be considered the first psychotherapist in the modern tradition in that he believed in "moral persuasion" in dealing with the mentally ill—that is, in simply talking with patients in an attempt to reason with them.

DUNBAR, HELEN FLANDERS (1902–1959) Dunbar demonstrated that psychosomatic disorders were emotional in origin and related the specific type of disorder to personality characteristics.

DUNCKER, KARL (1903–1940) Duncker's publications cover a broad range of subjects, including problem solving, perception, motivation, systematic psychology, and philosophical issues.

DUNNETTE, MARVIN D. (b. 1926) Dunnette developed procedures for selecting and appraising research scientists, sales personnel, and clerical employees.

EBBINGHAUS, HERMANN (1850–1909) Ebbinghaus was the first psychologist to investigate learning and memory experimentally. He invented the nonsense syllable procedure, which revolutionized the study of association and learning.

ECCLES, JOHN C. (b. 1903) Eccles, an interactionist and personalist, views the mind and brain as separate and distinct entities. He offered a "liaison between brain and mind hypothesis" to explain the interactive process.

EHRENFELS, CHRISTIAN VON (1859–1932) Ehrenfels was a forerunner of the Gestalt movement. Asch credits Ehrenfels and Wertheimer as the major influences on his use of Gestalt in social psychology.

EISDORFER, CARL (b. 1930) Eisdorfer has specialized in research on aging. He was founding editor of the *Annual Review of Gerontology and Geriatrics.*

ELKIND, DAVID (b. 1931) Elkind is perhaps best known for his attempt to extend, integrate, and apply Piagetian theories to educational and social problems of children and youths.

ELLIOTSON, JOHN (1791–1868) Elliotson practiced mesmerism at the University College Hospital in London with positive results and gave it professional acceptance. He treated patients suffering from a variety of nervous disorders and also employed hypnosis as an anesthetic.

ELLIS, ALBERT (b. 1913) After practicing psychoanalysis, Ellis rebelled against its dogma and inefficiency, experimented with several other methods, and started his own system, now known as Rational-Emotive Behavior Therapy (REBT).

ELLIS, HAVELOCK (1859–1939) Ellis concluded that homosexual behavior was congenital. Masturbation, he stated, was a legitimate source of mental relaxation. Ellis also objected to Freud's application of adult sexual terms to infants.

ENDLER, NORMAN S. (b. 1931) Endler's interaction model of anxiety postulates that trait and state anxiety are multidimensional and that interactions evoking state anxiety occur between persons and situations only when person factors and situational stress are congruent.

ENTWISTLE, NOEL J. (b. 1936) Entwistle implemented two 5-year programs of research on student learning in higher education. One involved psychometric tests to predict degree performance; another focused more on learning processes.

ERIKSON, ERIK H. (1902–1992) Erikson is known for his work in developmental psychology. He coined the term *identity crisis* and described the human life cycle as comprising eight stages.

ERON, LEONARD D. (b. 1920) Eron's longitudinal research with medical students had some influence on the reorganization of medical curricula at the time. His remarkable longitudinal study on the learning of aggression in children (whose 40-year follow-up he recently conducted) demonstrated that aggressive behavior is stable over time and across generations and that its development is affected by observational learning.

ESCALONA, SIBYLLE K. (b. 1915) Escalona's primary interest was normal development in infancy and early childhood. She was among the first to undertake extensive systematic studies of normal infant behavior in naturalistic settings.

ESDAILE, JAMES (1808–1859) Esdaile, a British surgeon, began practicing hypnosis in India after having read of Elliotson's work. He used hypnosis to induce anesthesia. In operations to remove scrotal tumors, Esdaile reported reducing mortality rates from 50 to 5 percent.

ESQUIROL, JEAN ÉTIENNE (1772–1840) A successor to Philippe Pinel, Esquirol was one of the first, if not the first, to apply statistical methods to clinical studies of the mentally ill.

ESTES, WILLIAM K. (b. 1919) Estes brought statistical theory to bear upon Guthrie's learning theory. He de-

veloped a statistical theory of learning predicated on the principle of contiguity.

EVANS, DWIGHT L. (b. 1944) Evans has had a longstanding clinical and research interest in depression. His research has focused on the neurobiology of stress and depression, and he conducted clinical drug trials specializing in depression and related mood disorders.

EVANS, RICHARD I. (b. 1922) Evans is best known as a pioneer in oral history, instruction via film and television, and human problem-oriented research (prejudice, juvenile delinquency, health) in social psychology.

EWALD, JULIUS RICHARD (1855–1921) Ewald was interested in the central nervous system and had a special interest in the physiology of receptor end organs. He developed the pressure-pattern theory of hearing, which challenged the resonance theory of Helmholtz.

EYSENCK, HANS J. (1916–1997) Eysenck researched the areas of personality theory and measurement, intelligence, social attitudes and politics, behavioral genetics, and behavior therapy. He was one of the pioneers in the development of behavior therapy in England.

FABRE, JEAN HENRI (1823–1915) Fabre described many aspects of insect behavior, including the relationship between the sex of the egg and the dimensions of the cell in the solitary bee. He opposed Darwin's theory of evolution.

FAIRBURN, CHRISTOPHER G. (b. 1944) One of the world's leading authorities on the treatment of Bulimia Nervosa. His model of the disorder underlies most cognitive-behavioral interventions for it.

FECHNER, GUSTAV THEODOR (1801–1887) Fechner is best remembered for his development of psychophysics. For the first time scientists could measure the mind; by the mid-19th century, the scientific methods were being applied to mental phenomena.

FERENCZI, SANDOR (1873–1933) Ferenczi was interested in the relationship between biology and psychoanalysis and extended the work of Freud.

FERRIER, SIR DAVID (1843–1928) Ferrier was noted for his contributions regarding the localization of brain functions. He was the first to locate the visual center in the occipital lobes, and his work led to important advances in brain surgery.

FERSTER, CHARLES B. (1922–1981) Ferster was dedicated to an operant behavioral approach to psychology. His writings and research ranged from basic behavioral research to its applications in education and clinical psychology.

FESTINGER, LEON (1919–1989) Festinger further developed cognitive dissonance theory, which states that people whose behavior is in discord with their thoughts will restructure their thoughts and behavior to mutual agreement.

FICHTE, JOHANN GOTTLIEB (1762–1814) Fichte was one of the successors to Kantian philosophy and psychology. He stressed the freedom of the human will in contrast to the determinism found in the physical sciences.

FISCHER, HARDI (b. 1922) Fischer is an experimental psychologist who was especially concerned with the relationships among visual perception, epistemology, and developmental psychology.

FISHER, RONALD A. (1890–1962) Fisher gave psychology the analysis of variance, analytic techniques for small samples, the concept of null hypothesis, and the notion of significant/insignificant as a continuum rather than a dichotomy.

FLAMENT, CLAUDE (b. 1930) Flament's publications covered various topics: social influence, in-group behavior, structural balance cognitive theory, qualitative data analysis, and ordered set theory.

FLAMMER, AUGUST (b. 1938) Flammer's research centered on question asking, selective memory, influence of titles, encoding, free discourse, perspective shifts, and individual differences.

FLAVELL, JOHN H. (b. 1928) Flavell's research style was to think of important cognitive competencies that others had not studied and then to investigate their development from childhood.

FLOURENS, PIERRE (1794–1867) Flourens confirmed the Bell-Magendie law—the separation of the nervous system into sensory and motor divisions.

FLOURNOY, THÉODORE (1854–1920) Flournoy was the initiator of scientific psychology in Switzerland, where he founded the first psychological laboratory. His research included studies on reaction time, imaging, sensation, and hypnosis.

FLÜGEL, JOHN CARL (1884–1955) Flügel's best-known work is *A Hundred Years of Psychology,* which reflects broad historical scholarship in psychology.

FOA, EDNA B. (b. 1942) Foa has devoted her academic career to studying the psychopathology and treatment of anxiety disorders, primarily Obsessive-Compulsive Disorder and Posttraumatic Stress Disorder. She is one of the world's experts in the treatment of these disorders.

FOPPA, KLAUS (b. 1930) Foppa has worked mainly in the field of verbal communication, especially on the development of children's communicative skills, for which he developed several methods of analysis.

FOREL, AUGUSTE-HENRI (1848–1931) Forel was the first to achieve biological preparations of human brain

specimens and was also the first to describe parabiosis (the joining together of two animals for experimental research).

FOWLER, RAYMOND D. (b. 1930) Fowler is recognized for his innovative work in computer interpretation of the MMPI. His system has been translated into most major European languages and is considered a prototype for other computer-based testing systems. He served effectively for many years as the executive director of the American Psychological Association.

FRAISSE, PAUL (b. 1911) Fraisse is best known for his contributions to time and rhythm psychology. He also has contributed considerably to the development of psychology as a science in France.

FRANK, ELLEN (b. 1944) Frank's work has focused on treatment and maintenance of obtained treatment effects for mood disorders. She has been a leader in the evaluation and modification of interpersonal psychotherapy.

FRANK, JEROME D. (b. 1909) Frank's major research has led to the formulation of the demoralization hypothesis, the concept that the main healing power of psychotherapy lies in features that combat demoralization. His most important work *Persuasion and Healing*.

FRANKL, VIKTOR E. (b. 1905) Frankl's logotherapy is predicated on "man's search for meaning," based to some degree on his experiences as an inmate of Nazi concentration camps, which he effectively survived.

FRANKLIN, BENJAMIN (1706–1790) Franklin showed that the afterimage will be positive on the dark field of the closed eye and negative when the eyes are open and fixed on a white piece of paper. He was better known for his intellectual contributions to early political development within the United States.

FRANZ, SHEPERD I. (1874–1933) Franz surgically removed parts of animals' brains to study the effects of their removal on behavior. Removing the frontal lobes of the animals' brains resulted in the loss of recently acquired habits.

FRENKEL-BRUNSWIK, ELSE (1908–1958) Frenkel-Brunswik is best known for her major part in *The Authoritarian Personality* and for her empirical delineation of the concept of intolerance of ambiguity.

FREUD, ANNA (1895–1982) The daughter of Sigmund Freud, she was a specialist in children's psychoanalysis who championed the needs of children, applying her father's theories.

FREUD, SIGMUND (1856–1939) Freud developed a personality theory explaining human motivation and expanded his theory to include more than just treatment for the disturbed. He consistently ranks among the most influential writers in history.

FRIJDA, NICO H. (b. 1927) Frijda developed a general theory of emotion, integrating the study of emotion into the information-processing framework, while still supporting phenomenological and clinical viewpoints.

FRISCH, KARL VON (1886–1982) Von Frisch is best known for his study of communication in honeybees. He isolated the visual, olfactory, and gustatory cues involved in the communication, and demonstrated that honeybees navigate by using the sun for orientation.

FROEBEL, FRIEDRICH (1782–1852) Froebel believed that the goal of education was to develop or unfold the innate potential of the individual. The child was assumed to be inherently good; thus, all human evil arises from wrong educational methods.

FROMM, ERICH (1900–1980) Fromm acknowledged humankind's biological past, but he stressed humankind's social nature. The general theme of productive love permeates much of Fromm's writings.

FROMM, ERIKA (1910–2003) Fromm is best known for developing an ego psychological theory of hypnosis. She frequently referred to herself as a "rebel against orthodoxy," referring to Freud's psychoanalytic theory.

GAGNÉ, ROBERT M. (b. 1916) Gagné performed a series of studies on the acquisition of knowledge and distinguished motor and sensory nerves. He also identified learning hierarchies and mathematics learning.

GALEN (ca. 130–200) Galen codified the then extant knowledge of medicine, anatomy, and medically pathological personalities into general personality theory (the humoral theory). He developed a more systematic classification system than had previously been utilized.

GALL, FRANZ JOSEF (1757–1828) Gall is credited with being a pioneer in brain mapping or brain localization. Phrenology's basic premise, however, was invalidated when it was discovered that the skull and the brain's topography are not in accord.

GALTON, FRANCIS (1822–1911) Galton made seminal contributions in a variety of fields: classification of fingerprints, genetics, statistics, anthropometry, and psychometry. He was the first scientist to formulate clearly the nature-nurture question.

GALVANI, LUIGI (1737–1798) Galvani investigated electrical phenomena in animal organisms. His work stimulated many further developments in the understanding of electrical phenomena in living organisms.

GARCIA, GUILLERMO DAVILA (1902–1968) Garcia's fundamental research and teaching interest was in psychopathology. He founded the first Latin American group of cross-cultural studies.

GARCIA, JOHN (1917–1986) Garcia is known for his studies on selective and adaptive learning mechanisms and the modification of predatory behavior with conditioned taste aversions.

GATZ, MARGARET (b. 1944) Gatz has made major contributions to the area of behavioral medicine. She is especially well known for her work among older adults.

GEMELLI, AGOSTINO (1878–1959) Gemelli was attracted to sociology, philosophy, and religion. He initiated and stimulated new areas of research, and he gave Italian psychology a stronger sense of identity and respectability.

GERMAIN, JOSÉ (1897–1986) Germain established scientific psychology in Spain in the early 1930s. He promoted the study, adoption, and application of psychological tests.

GESELL, ARNOLD L. (1880–1961) Gesell greatly influenced child-rearing practices in the 1940s and 1950s. He took a strictly constitutional or physiological approach in which cultural or learning factors played little part.

GIBB, CECIL A. (b. 1913) Gibb's major contributions have been to university administration and educational leadership. His publications have been in the areas of personality, leadership, and executive behavior.

GIBSON, ELEANOR J. (1910–2002) Gibson's research has embraced learning in humans and animals, studies of controlled rearing in animals, development of reading skills, and especially perceptual development in infants and young children.

GIBSON, JAMES J. (1904–1979) Gibson is primarily known for his research and theories of perception. He became a leader of a new movement by considering perception to be direct, without any inferential steps, intervening variables, or associations.

GILBRETH, FRANK B. (1868–1924) Gilbreth analyzed bricklaying to determine the best way of doing it. In his book *Motion Study,* he extended the micromotion study to other areas of construction work.

GILBRETH, LILLIAN E. (1878–1972) Gilbreth applied motion study to household management. She also offered seminars on general micromotion principles.

GLASSER, WILLIAM (b. 1925) Glasser formulated reality therapy, which states that persons are born with basic needs, the primary being the need to belong and to be loved and the need to gain self-worth and recognition.

GODDARD, HENRY H. (1866–1957) An early student of the causes of mental retardation, Goddard argued for hereditary intelligence and was an advocate of eugenics.

GOETHE, JOHANN WOLFGANG VON (1749–1832) Goethe influenced psychology in two different areas: color vision and the theories of Sigmund Freud. He mistrusted experimentation but had great faith in intuitive observation.

GOLDSTEIN, KURT (1878–1965) Goldstein developed a set of tests to measure the loss of abstract attitude in patients with organic brain disease. He observed that brain-injured patients tended to persevere when pushed to perform tasks they could no longer do.

GOODENOUGH, FLORENCE L. (1886–1959) Goodenough was most widely known for the Draw-a-Man Test, which asks the child to draw a figure. This test is scored not for artistic ability but for the presence of details.

GOODWIN, FRED (b. 1936) A major leader in the discovery of patterns of etiology and treatments for Bipolar Disorder.

GORMAN, JACK M. (b. 1951) Gorman's research interests include the neuroanatomy and neurotransmitter function in Panic Disorder, the neuroendocrinology of depression, and the neuroimmunology of Schizophrenia.

GOSSETT, WILLIAM S. (1876–1937) An English statistician and pioneer in the development of modern statistical methods, Gossett derived the statistic t (Student's t), widely used in tests of differences among means of small samples.

GOUIN DÉCARIE, THÉRÉSE (b. 1923) Gouin Décarie designed the first operational scale to assess cognitive development in infancy.

GRACE, ANTHONY A. (b. 1955) Grace's research has focused on the physiology and anatomy of the dopaminergic system and its postsynaptic targets in the basal ganglia, thalamus, and cortex, with an emphasis on the system's role in Schizophrenia. His first major contribution to the field of Schizophrenia research was the discovery of antipsychotic drug-induced depolarization block in dopamine cells.

GRAHAM, FRANCES (b. 1918) Graham related physiological changes in autonomic and brain activity to perceptual-cognitive function, especially during early development.

GREENOUGH, WILLIAM T. Greenough is regarded as the major figure in the research that concluded that the formation of new synaptic connections between nerve cells was a fundamental aspect of memory storage in the brain.

GREGORY, RICHARD L. (b. 1923) Gregory undertook studies on size constancy during motion. He developed the notion that perceptions are predictive hypotheses, somewhat like scientific hypotheses.

GRONER, RUDOLF (b. 1942) Groner's main work is a "generalized hypothesis theory" of cognitive activity. In its most general form, a series of model variants are con-

structed by specifying assumptions in a systematic and exhaustive way.

GUILFORD, JOY PAUL (1897–1987) Guilford made numerous factor analytic investigations of personality traits, including intellectual abilities, culminating in his structure-of-intellect model.

GUILLAUME, PAUL (1878–1962) Guillaume concentrated mostly on child psychology and on the study of anthropoids. He wrote on the epistemology of scientific psychology, which helped strengthen the foundations of this discipline.

GUION, ROBERT M. Guion has been a leader in the development of industrial psychology and organizational behavior. He has served as a mentor for numerous leaders in organizational and industrial psychology.

GULLIKSEN, HAROLD O. (1903–1996) Gulliksen studied mathematical psychology. As an examiner in social sciences, he was part of a group that developed objective tests for college-level courses.

GUTHRIE, EDWIN R. (1886–1959) Guthrie was a learning theorist. He stated that learning is simply a matter of a stimulus-response association by contiguity.

GUTTMAN, LOUIS H. (1916–1987) Guttman's positions relate to his major interest in psychometrics, nonparametric analysis, and social psychology.

HAGA, JUN (b. 1931) Haga incorporates the study of language into the theory and practice of teaching. He holds that meaning is conveyed by logical and emotive functions of language.

HALL, CALVIN S. (1909–1985) Hall's contributions to the study of dreams are the application of quantitative content analysis to large samples of dreams and a cognitive theory of dreams and dream symbolism. He wrote extensively about personality theory and theorists.

HALL, G. STANLEY (1844–1924) Hall founded and promoted organized psychology as a science and profession, especially with APA. He also was involved in many aspects of child development and education. He brought Freud to the United States to speak to leaders in the field of psychology.

HALL, MARSHALL (1790–1837) Hall distinguished voluntary activities from conscious ones, which are dependent on the higher centers of the brain.

HAMILTON, SIR WILLIAM (1788–1836) In revolt against the British associationists, Hamilton held that the first principle of psychology was the unity and activity of the human mind.

HARLOW, HARRY F. (1905–1981) Harlow is best known for his studies on infant monkeys raised with surrogate mothers. He found that extended social deprivation led to severe disruption of later social behavior.

HARTLEY, DAVID (1705–1765) Hartley is considered the founder of British associationism. He was one of the earliest physiological psychologists to attempt to relate association of ideas with brain vibrations.

HATFIELD, ELAINE C. (b. 1937) Hatfield's main contribution is theorizing and researching areas once thought to be impossible to investigate: passionate and compassionate love, intense emotion, and interpersonal equality.

HEALY, WILLIAM (1869–1963) Healy developed performance tests to supplement the Stanford-Binet Intelligence Scale, of which the Healy Picture Completion Test is perhaps the most widely known and used. He pioneered in the establishment of guidance clinics for problem children; these clinics were frequently located at university settings.

HEBB, D. O. (1904–1985) Hebb's experiments confirmed the importance of early experience in the growth of mind and intelligence and, at maturity, the continued need of exposure to a normal sensory environment for mental health.

HECHT, SELIG (1892–1947) Hecht showed that the smallest amount of light that can be detected under the most ideal viewing conditions is very close to the physiological limit.

HECKHAUSEN, HEINZ (1926–1988) Heckhausen constructed TAT measures for the independent assessment of "hope of success" and "fear of failure." These measures became the base of the rapidly growing German achievement motivation research.

HEGEL, GEORGE FRIEDRICH (1770–1831) Hegel saw reason, not experience, as the first principle. Modern notions of self-consciousness, self-actualization, consciousness raising, and self-concern are direct outgrowths of neo-Hegelian idealism.

HEIDBREDER, EDNA (1890–1985) Heidbreder's varied interests included schools, systems, and theories of psychology; the psychology of cognition; and testing and measurement.

HEIDEGGER, MARTIN (1889–1976) Heidegger is considered to be the bridge between existential philosophy and existential psychology. He believed that humans must accept that death is inevitable and nothingness will follow.

HEIDER, FRITZ (1896–1988) Heider worked in Kurt Koffka's research laboratory on problems related to deafness. His concepts are found in his book *The Psychology of Interpersonal Relations*.

HELMHOLTZ, HERMANN VON (1821–1894) Helmholtz formulated the mathematical foundation for

the law of conservation of energy. He influenced the experimental approach to psychological problems, especially in perception and sensation.

HERBART, JOHANN FRIEDRICH (1776–1841) Herbart believed that the mind could be a compound of smaller units. He brought to psychology the notion that the mind could be quantified and influenced Wundt and Freud with his book.

HERING, EWALD (1834–1918) Hering fostered the doctrine of nativism, the view that one can judge space and depth in an inherent way. The Gestalt psychologists later took up this idea.

HERRMANN, THEO (b. 1929) Herrmann is best known for his work in cognitive psychology, psychology of language, and philosophy of psychological science.

HILGARD, ERNEST R. (1904–2001) Hilgard's research interests were primarily in the psychology of learning and motivation, and after World War II he focused his attention on social psychology and hypnosis research.

HINDE, ROBERT A. (b. 1923) Hinde's work on bird behavior entailed comparative studies of courtship behavior, analysis of motivational conflicts, and the study of habituation.

HIPPOCRATES (460–377 B.C.) Hippocrates took Thales' four elements (earth, air, fire, water) and related them to their four corresponding bodily humors (black bile, blood, yellow bile, phlegm).

HIRSCH, JULES Hirsch has worked on clinical research related to the physiology of appetite and eating disorders.

HOBBES, THOMAS (1588–1679) Hobbes is considered the father of British empiricism and associationism. Influenced by Galileo's concept of motion, he concluded that psychological (mental) activities were motions in the nervous system.

HÖFFDING, HARALD (1843–1931) Höffding believed that mental functions could best be understood through simplicity and identity, analysis, and synthesis. He viewed the central fact of psychology as being the will.

HOLLINGWORTH, HARRY L. (1880–1956) Hollingworth employed reintegration as a general principle and saw it as the basis of an improved association psychology.

HOLLINGSWORTH, LETA S. (1886–1939) Hollingsworth's interests centered upon children. Her work emphasized the fact that children with serious problems and children with high intelligence may suffer from emotional difficulties that worsen in adolescence.

HOLT, EDWIN B. (1873–1946) An early behaviorist, Holt believed strongly that psychology should study "the specific response relationship."

HOLT, ROBERT R. (b. 1917) Holt strove to integrate the best of the two approaches of clinical and statistical prediction.

HORAS, PLÁCIDO A. (b. 1916) Horas endeavored to establish integrative bonds between discordant trends in contemporary psychology. He believed that psychology should emanate from a biophysical conception of human behavior, emphasizing its cognitive aspects.

HORNEY, KAREN D. (1885–1952) Horney abandoned the standard Freudian orthodoxy because of the issue of female sexuality. She stated that Freud's stress on the sexual instinct was completely out of proportion. She developed her own theory of neuroticism, which has had a major impact on verbal psychotherapy.

HORST, A. PAUL (b. 1903) Horst's goal was to solve complex human problems using rigorous mathematical and quantitative techniques rather than rhetoric and semantics.

HOSHINO, AKIRA (b. 1927) Hoshino is best known for his study of culture shock, a review and critical theory of sojourners' assimilation and adjustment to a new culture and reentry into their own culture after a long stay abroad.

HOVLAND, CARL L. (1912–1961) Hovland is credited with numerous contributions, primarily to social psychology, among them the sleeper effect, communicator credibility, the preferred value of stating a conclusion, and valuable effects due to the order of presenting propaganda.

HULL, CLARK L. (1884–1952) Hull's most important contribution to psychology lies in his theory of learning, considered one of the most important theories of the twentieth century.

HUME, DAVID (1711–1776) In the *Treatise of Human Knowledge* Hume wrote: "Mind is nothing but a bundle or collection of different perceptions unified by certain relations and suppos'd tho' falsely to be endowed with a perfect simplicity and identity."

HUNT, J. McVICKER (1906–1991) Best known for his two-volume publication *Personality and Behavior Disorders,* Hunt referred to himself as an interactionist and not an environmentalist. He was one of the last general psychologists.

HUNT, THELMA (1903–1992) Hunt's research was in the personnel psychology field, where she developed tests to meet problems stemming from the Civil Rights Act and government regulatory and court measures relating to tests.

HUNTER, WALTER S. (1889–1953) Hunter believed that an objective, behavioristic approach to psychology should not continue to be used with a subject matter imposed on it by philosophy.

HUSSERL, EDMUND (1859–1938) Husserl was the founder and most prominent exponent of *phenomenology,* which affirmed that philosophical inquiry begins with the phenomena of consciousness, and only phenomena of consciousness can reveal to us what things essentially are.

HYMAN, STEVEN E. (b. 1952) Hyman, past director of the National Institute of Mental Health, directed an active research program in molecular neurobiology, focusing on how neurotransmitters, especially dopamine and glutamate, alter the expression of genes in the striatum and thereby produce long-term changes in neural function that can influence behavior.

IKEDA, HIROSHI (b. 1932) Ikeda believes that the most essential thing in psychological study is scientific data collection and measurement, and because Japanese psychology needed more systematic disciplines, he devotes himself to promoting the scientific ideas of research.

IRITANI, TOSHIO (b. 1932) Iritani launched a new field of psycholinguistics. In his *New Social Psychology,* he proposed a broad, integrative unification of social psychological phenomena in the areas of politics, economy, population, geography, and history.

ITARD, JEAN-MARC-GASPARD (1775–1838) Itard was a pioneer in the study of mental deficiency, having attempted to train Victor, the so-called wild boy of Aveyron. Although his efforts with Victor met with little success, he developed methods that proved useful in training individuals with limited intellectual abilities.

IWAO, SUMIKO FURAYA (b. 1935) Regarding the relationship between the knowledge about and attitude toward foreign people, Iwao's findings suggest a linear positive relationship between knowledge and attitude, whereas if the amount of knowledge is large the relationship is negative.

JAENSCH, ERICH R. (1883–1940) Jaensch is best known for his work on eidetic imagery. He proposed two biotypes: The B-type was a vivid memory image under voluntary control; the T-type, which was not under voluntary control, he believed to be related to under activity of the parathyroid.

JAHODA, MARIE (1907–2001) Two connecting threads were inherent in Jahoda's professional life: preventing social psychology from splitting into psychological and sociological branches and engaging in problem-centered rather than method-centered work.

JALOTA, SHYAM SWAROOP (b. 1904) Jalota is best known for his pioneering work for standardized tests of general mental ability in Hindi. He formulated a hypothesis that "each human experience carries within it the active or latent seeds of contrary impulses."

JANET, PIERRE (1859–1947) Janet developed a system of psychology and psychopathology that he called "*psychologie de la conduite*" (psychology of conduct or behavior). A decrease in psychic energy was a central belief in Janet's explanation of mental disorders.

JANIS, IRVING LESTER (1918–1990) According to the Janis-Feisrabend hypothesis, an argument is most effective when the positive side is advanced before the negative. Also, he demonstrated experimentally that hostile individuals are less susceptible to persuasion.

JAMES, WILLIAM (1842–1910) James is considered America's greatest psychologist because of his brilliant clarity of scientific writing and his view of the human mind as functional and employing adaptive mental processes, in opposition to Wundt's analysis of consciousness into elements.

JAMISON, KAY REDFIELD (b. 1946) Jamison is best known for her historical research demonstrating that many famous poets, writers, and musicians suffered from Bipolar (manic-depressive) Disorder. In *An Unquiet Mind* she describes her own experience with Bipolar Disorder.

JASPERS, KARL (1883–1969) Jaspers distinguished three modes of being: being-there, being-oneself, and being-in-itself. Being-there referred to the objective, real world. Being-oneself meant one's personal existence. Being-in-itself involved an ability to transcend the known world and to know other worlds.

JASTROW, JOSEPH (1863–1944) Jastrow wrote about the occult, psychic research, mental telepathy, spiritualism, and hypnosis. He was, at least in part, a believer in psychic phenomena. He attacked Freudian theory, likening it to a house built of playing cards.

JENNINGS, HERBERT S. (1868–1947) Jennings's work was particularly important to psychology in two areas: He disproved the local action theory of tropisms, and he also demonstrated that mutations were likely to involve very small changes in organisms.

JENSEN, ARTHUR R. (b. 1923) Jensen hypothesized that both individual and racial differences in abilities are in part a product of the evolutionary process and have a genetic basis. His ideas came to be termed *jensenism,* often pejoratively.

JING, QUICHENG (b. 1926) Jing's books *Colorimetry* and *Human Vision* were the first books on visual science in China. He also has published studies of the psychological development of Chinese children.

JOHN, ERWIN R. (b. 1924) John is known for his material theory of memory. He hypothesized a statistical configuration theory of learning based on Lashley's conclusions. John also argued for mass action rather than learning centers in the brain.

JOHNSON, VIRGINIA (b. 1925) Johnson is credited, along with her colleague Masters, for helping to bring sex therapy to the forefront of psychology.

JONES, MARY COVER (1896–1987) Jones is most prominent as the first researcher to remove a fear in a child—the case of Peter. She worked with the preeminent behaviorist J. B. Watson, who had left psychology for personal reasons and followed a career in business.

JUDD, CHARLES H. (1873–1946) Judd studied the process of reading by photographing eye movements. He described how number consciousness was a function of reasoning and other high mental processes.

JUDD, LEWIS L. (b. 1930) Judd is an expert in biological psychiatry and clinical psychopharmacology, and his extensive research contributions include investigations into the effects of psychopharmacological agents on both brain mechanisms and symptom patters of depression, Bipolar Disorder, and Schizophrenia.

JUNG, CARL (1875–1961) Jung's personality system included three levels of the psyche: (a) the ego, (b) the personal unconscious, and (c) the deeper collective unconscious. He suggested that therapy include a great deal of dream interpretation. More recently, his theory has served as the basis for personality subtyping.

KAGAN, JEROME (b. 1929) Kagan has researched various aspects of the development of children, including variation in the cognitive styles called reflectivity and impulsivity, and the maturation of memory, self-awareness, and moral sense over the first 2 years of life.

KALIN, NED (b. 1951) Kalin has provided remarkable data in a series of experiments related to the biology of emotion using nonhuman primates.

KAMIYA, JOE (b. 1925) Kamiya's research involves the psychophysiology of consciousness and heightened awareness, altered states of consciousness, and transpersonal consciousness.

KANDEL, ERIC R. (b. 1929) Kandel is Nobel Laureate for his work on the nature of synaptic transmission in Aplysia, an invertebrate, and how such processes modulate transmission in higher organisms.

KANT, IMMANUEL (1724–1804) Kant rejected the view of the mind as mental substance. For him, mental processes could not be measured because they had only the dimension of time, not space. Psychology could never be an experimental science.

KANTOR, JACOB R. (1888–1984) Kantor proposed a systematic psychology called interbehaviorism. It shares with the behavioristic tradition a denial of mind or mental activity in favor of an objective approach.

KATONA, GEORGE (1901–1981) Katona's major contributions are his studies of consumer expectations and behavior found in such works as *Aspirations and Affluence, A New Economic Era,* and *Essays on Behavioral Economics.*

KATZ, DAVID (1884–1953) The same color, Katz discovered, can appear to the viewer in different modes, such as surface or film color, or as bulky, shiny, transparent, or luminous. His findings demonstrated the influence of the total visual field on color perception.

KAZDIN, ALAN E. (b. 1945) A majority of Kazdin's work has focused on treatment of aggressive and antisocial children referred for inpatient or outpatient treatment. His contributions to the field of psychology reflect the melding of intervention research with his interests in evaluation methodology.

KELLER, FRED S. (1899–1996) Keller was a psychologist who applied principles of operant conditioning to real-life human behavior. Much of his work centered on educational techniques to improve classroom learning and memory of learned materials.

KELLER, MARTIN (b. 1946) Keller is a leader in long-term studies of the course and treatment of mood and anxiety disorders.

KELLEY, HAROLD H. (b. 1921) Kelley's major contributions, all in social psychology, have been to the theory of small groups, including attribution theory dealing with the perception of causes of behavior, and to the study of close relationships.

KELLOGG, WINTHROP N. (1898–1972) When their son Donald was 10 months old, Kellogg and his wife Luella obtained a 7-month-old chimpanzee, who was then raised as a sibling. Despite equal treatment, the son surpassed the ape after 9 months.

KELLY, GEORGE A. (1905–1967) Kelly's theory of *personal constructs* is a broad, inclusive personality theory based on the notion that each individual attempts to anticipate and control his or her environment.

KELLY, LOWELL E. (1905–1986) Kelly instituted a longitudinal study of 300 engaged couples that lasted from 1939 to 1980. One of his conclusions was that marital compatibility is due to only a small function of sex and social attributes.

KIERKEGAARD, SOREN A. (1813–1855) Kierkegaard anticipated depth psychology, depersonalization, and the crisis of the will. He understood the peculiar modern malaise of "spiritlessness." He is best known as a Scandinavian philosopher.

KIESOW, FEDERICO (1858–1940) Among the many areas researched by Kiesow are taste, sensitivity, thermic and tactile points, geometric illusions, the Weber-Fechner Law, eidetic imagery, psychophysics, and the specific function of the sense organs.

KILTS, CLINTON D. (b. 1951) Kilts's major accomplishments include the further contribution of novel methods and approaches in neurochemistry and drug monitoring, including a careful and comprehensive description of the pharmacology, regulation, anatomy, and stress reactivity of dopamine-containing neurons innervating the rodent amygdaloid complex.

KINSEY, ALFRED C. (1894–1956) The Kinsey reports provided the first quantified, thorough description of many diverse human self-reports of sexual experience. The data also put to rest many misconceptions about sexuality. Recently Kinsey's work and the institute he founded have come under heavy criticism.

KINTSCH, WALTER (b. 1932) Kintsch, director of the Institute of Cognitive Sciences at the University of Colorado, played a major role in the transition from learning theory to cognitive psychology.

KLAGES, LUDWIG (1872–1956) Klages believed that the body and soul interacted and that the point of this interaction was the human personality. An individual personality was a system of dynamic relationships.

KLERMAN, GERALD (1928–1992) Klerman was among the most influential American psychiatrists. In addition to playing a major role in government mental health policies, he codeveloped interpersonal psychotherapy with his wife, Myrna Weissman.

KLINEBERG, OTTO (1899–1992) Klineberg described differences in various psychological characteristics such as intelligence, emotions, and personality in various races including the Chinese, Native Americans, and African Americans. His general conclusion was that these differences are by and large culturally determined.

KLOPFER, BRUNO (1900–1971) Klopfer's major work was *The Rorschach Technique.* It became the single most authoritative source on the Rorschach test.

KLÜVER, HEINRICH (1897–1979) Klüver developed the method of equivalent and nonequivalent stimuli for studying behavior and determined the role of the brain, particularly the striate cortex, in vision.

KOCH, SIGMUND (1917–1996) Koch argued that psychology is not a coherent science but rather a collectivity of discrete and often incommensurable psychological studies, many of which require methods more like those of the humanities than the natural sciences.

KOFFKA, KURT (1886–1941) Koffka was a founder of the Gestalt psychology movement; of the three founders (Koffka, Kohler, and Wertheimer), he was particularly noted for his extensive publications.

KOHLBERG, LAWRENCE (1927–1987) Kohlberg is best known for his research on moral development in children. Following the lines of Piaget, Kohlberg stated that children followed moral development in three stages.

KÖHLER, WOLFGANG (1887–1967) Köhler, along with Wertheimer and Koffka, was a founder of the Gestalt psychology movement, of which he was particularly noted as the public spokesman.

KONORSKI, JERZY (1903–1973) Konorski pursued his life's pervading goal, to learn "how the brain works," formulated when he was about 20 years of age. His most important book was *Integrative Activity of the Brain.*

KOOB, GEORGE F. Koob is known as an authority on the neurobiology of emotional behavior, addiction, and stress. His investigations have provided significant information about the CNS action of drugs and the neuropharmacological basis of psychopathology.

KORNADT, HANS-JOACHIM (b. 1927) Kornadt has specialized in cross-cultural research, particularly concerning the development of aggression.

KRAEPELIN, EMIL (1855–1926) Through careful observation of many patients and statistical tabulation of symptoms, Kraepelin concluded that there were two major mental disorders: dementia praecox and the manic-depressive psychosis. His work on classification eventually served as a model for the *Diagnostic and Statistical Manual* of the American Psychiatric Association.

KRAFFT-EBING, RICHARD VON (1840–1902) *Psychopathia Sexualis* is Krafft-Ebing's best-known work. He took a purely constitutional approach. All sexual variations were based on genetic defects, but masturbation could hasten or even produce disorders.

KRASNER, LEONARD (b. 1924) Influenced particularly by the experimental orientation of Fred Keller, Krasner's research efforts focused on the development of a behavioral approach in clinical psychology. Along with Leonard Ullmann, he published the first text in abnormal psychology to offer a systematic behavioral model.

KRETSCHMER, ERNST (1888–1964) Kretschmer is best known for his typology within the framework of constitutional psychology: Body structure/physiology determines personality.

KRISHNAN, K. RANGA RAMA (b. 1956) Krishnan's work has focused primarily on neurobiological dysfunctions associated with mood disorders and Alzheimer's disease. A major effort of his collaboration has been to investigate the structural changes that occur among depressed elderly humans.

KÜLPE, OSWALD (1862–1915) Külpe began to believe that the analysis of consciousness involved more than what Wundt had suggested. He concluded that thinking could occur in the absence of mental images or sensations and termed this *imageless thought.*

KUPFER, DAVID J. (b. 1941) Kupfer has made major contributions to the understanding of mood disorders. His work on sleep dysregulation as it relates to depression is particularly noteworthy.

LADD, GEORGE TRUMBULL (1842–1920) Ladd believed that consciousness should operate to solve problems, although he granted that there is a biological side to the nervous system. From his view, the function of the mind is to adapt, and in adapting it must look to the future.

LADD-FRANKLIN, CHRISTINE (1847–1930) Ladd-Franklin is best known for her theory of color vision. Her theory is based on that of F. C. Donders, but with a developmental or genetic focus.

LAMARCK, JEAN-BAPTISTE DE MONET DE (1744–1829) Lamarck developed the theory of evolution. One of his views accounted for the inheritance of acquired characteristics, which Lamarck thought was necessary to explain cumulative changes.

LA METTRIE, JULIEN OFFROY DE (1709–1751) La Mettrie saw humans as machines, which gives him a place in the history of behaviorism. In his later years he developed the doctrine of hedonism, asserting that pleasure is the goal of life and that all motivation is selfish.

LANG, PETER (b. 1930) Lang's early work concerned models of anxiety and behavior therapy. Over his career he expanded his model of human behavior and examined the relationship of cognitive and psychophysiological functioning.

LANGE, CARL GEORG (1834–1900) Unlike W. James, Lange distinguished emotion from passion. He believed that emotions included joy, sorrow, fear, and anger, while passions referred to love, hate, and admiration.

LASHLEY, KARL (1890–1958) Lashley formulated two principles of brain functioning: mass action and equipotentiality.

LAZARUS, ARNOLD A. (b. 1932) Lazarus is the developer of multimodal therapy based on the simultaneous consideration of Behavior, Affect, Sensation, Imagery, Cognition, Interpersonal relations, and Drugs (BASIC-ID) for both diagnosis and treatment of psychological disorders.

LAZARUS, RICHARD S. (1922–2003) Lazarus mounted efforts to generate a comprehensive theoretical framework for psychological stress and undertook programmatic research based on these formulations.

LE BON, GUSTAVE (1841–1931) Le Bon developed a doctrine of the hierarchy of races. The criteria he set up involved the degree of reasoning ability, power of attention, and mastery of instinctual needs.

LEE, CHANG-HO (b. 1936) Lee has been developing an Oriental model of counseling and psychotherapy. The emphasis in his model includes educative dialogue, integrational approach, tolerance training, asset reinforcement, and enhancing social interest.

LEIBNITZ, GOTTFRIED WILHELM (1646–1716) Leibnitz believed that mind and body followed their own laws in perfect agreement. Leibnitz's parallelism was one solution to the mind-body problem that has concerned philosophers and psychologists for centuries.

LEONTIEV, ALEKSEI (b. 1903) Leontiev believed in the cultural-historical theory, which attempted to use Marxist doctrine as a basis for human development. Besides accounting for human psychological processes, the theory held that when persons interact, psychological processes develop.

LERNER, ARTHUR (b. 1915) Lerner regards all literary genres as vital sources for understanding behavior; he holds that one's cognitive and unconscious understanding is shaped by the language, symbols, metaphors, and similes that influence one's growth and development.

LERNER, RICHARD M. (b. 1946) Lerner is currently a leading developmental psychologist. He was one of the first psychologists to write about plasticity of the developing brain.

LEVY, STEVEN Levy is one of the leaders of psychoanalysis. He was recently appointed editor of the *Journal of the American Psychoanalytic Association.*

LEWIN, KURT (1890–1947) Lewin developed a topological vectoral psychology. Topology investigates the properties of space; vectors consider forces or dynamics.

LIÉBAULT, AMBROISE-AUGUSTE (1823–1904) Liébault's use of hypnosis marked the beginning of psychotherapy. Along with H. Bernheim, he founded the Nancy School and treated patients with hypnosis. He argued that hypnosis was a matter of suggestion.

LIEBERMAN, JEFFREY (b. 1948) Lieberman is a pioneer researcher in the area of first episode of Schizophrenia and its treatment.

LINDZEY, GARDNER (b. 1920) Lindzey is best known for his contributions to the fields of personality, social psychology, and behavior genetics. His book *Theories of Personality* (coauthored with C. S. Hall) was the first of its kind, leading the way for many others and for courses designed after this landmark publication.

LINEHAN, MARSHA M. (b. 1943) Linehan's primary research is in the application of cognitive and behavioral models to suicide behaviors, drug abuse, and Borderline Personality Disorder. She is best known for developing Dialectical Behavior Therapy.

LOCKE, JOHN (1632–1704) Locke was the first of the British empiricists and bridged the gap between the ra-

tional continental philosophers such as Descartes, Leibnitz, and Spinoza. He helped to promote a new attitude toward knowledge that was fostered in the upcoming empirical tradition.

LOEB, JACQUES (1859–1924) Loeb's theory of the tropism as applied to animal behavior represented a return to the mechanistic view set forth earlier by René Descartes, which stated that animals acted like machines.

LORENZ, KONRAD (1903–1989) Lorenz never conducted a formal experiment, and his descriptive observations were often anecdotal. He infuriated his more conventional colleagues by saying, "If I have one good example, I don't give a fig for statistics."

LOTZE, HERMANN (1817–1881) Lotze is known for his doctrine of local signs, typical of nineteenth-century thought, in which philosophical concepts, rather than empirical data, dominated the interpreted physiology of sense organs.

LUNDIN, ROBERT W. (b. 1920) Lundin's book *An Objective Psychology of Music* was a protest against the mentalistic approaches to the psychology of music presented by Carl Seashore and Max Schoen. He attempted to establish musical behavior on firm empirical grounds.

LURIA, ALEXANDER R. (b. 1902) Luria developed theories of language disorders and of the functions of the frontal lobe. He believed that cell groups must be organized in systems of zones working in concert, each performing its role in the complex system.

MACCOBY, ELEANOR E. (b. 1917) Maccoby is best known for her work on gender differences and the role of parent-child relationships on socialization.

MACCORQUODALE, KENNETH (1919–1986) MacCorquodale's career was intertwined with that of P. Meehl in their combined work in the philosophy of science and learning theory, most notably that of E. C. Tolman. MacCorquodale and Meehl are well known for their joint article "On a Distinction between Hypothetical Constructs and Intervening Variables."

MACH, ERNST (1838–1916) Mach has been identified as a positivist and believed that sensations were the data of all science. In his view, all science is observational, and the primary data of observation are sensations.

MAGENDIE, FRANÇOIS (1783–1855) Magendie contended that the seat of sensations was in the spinal cord and that the cerebrum perceived the sensations from the cord. This being the case, the cerebrum could reproduce the sensations, thus accounting for memory.

MAHER, BRENDAN A. (b. 1924) Maher's early work was focused on the model of motivational conflict as the origin of neurotic behavior. Later, he investigated the nature of language disturbances found in the schizophrenias. In 1970, Maher wrote a seminal paper demonstrating that the prevailing belief that delusions arise from a basic defect in reasoning was not consistent with the empirical evidence.

MAIER, STEVE (b. 1941) Maier, an experimental psychologist, has been a leader in development of neuroscience. He earlier studied learned helplessness, but more recently he has investigated stress and neural pathways.

MAIMONIDES, MOSES (1135–1204) Maimonides rejected the notion of a personal immortality. For him, the capacity for individual thinking disappeared with the destruction of the body, yet an individual might increase in understanding and knowledge and so attain a kind of immortality.

MAKARENKO, ANTON SEMYONOVICH (1899–1939) Makarenko's *The Road to Life* has been cited by most Soviet psychologists. His work developed a theory that became the basis of Soviet personality research and educational practices.

MALEBRANCHE, NICOLAS de (1638–1715) De Malebranche rejected Descartes's interactionism in favor of the doctrine of occasionalism. According to this view, one event does not cause another but is simply an occasion for God, the cause of all things, to cause the second event to occur.

MARLATT, ALAN (b. 1941) A leading authority on behavioral interventions and relapse prevention of alcoholism.

MARX, KARL HEINRICH (1818–1883) The starting point of Marx's socialism is the doctrine of class struggle. This provided the key to two of his most widely known doctrines: a materialist conception of history and the theory of surplus value.

MARX, MELVIN H. (b. 1919) Marx's research interests generally focused on various problems in the fields of learning and cognition. He contributed to our understanding of how human subjects are able to judge the frequencies with which events have occurred. His later work called attention to the pervasiveness and significance in everyday life of the inference process.

MASLOW, ABRAHAM H. (1908–1970) Maslow considered his basic approach to psychology to fall within the broad range of humanistic psychology, which he characterized as the "third force" in American psychology, the other two being behaviorism and psychoanalysis.

MASTERS, WILLIAM (1916–2001) With his colleague, Johnson, Masters conducted seminal work on sexual functioning and dysfunctions. Their work has clarified various myths regarding sexuality, and it has served as a basis for much of sex therapy.

MATARAZZO, JOSEPH D. (b. 1925) The foci of Matarazzo's research include intellectual and neuro-

psychological functioning, nonverbal indices of empathy and related psychological processes, and the role of lifestyle risk factors in health and illness.

MAY, ROLLO (b. 1909) May is known for his vanguard leadership in humanistic psychology, articulating existential tenets of the *encounter, choice, authenticity, responsibility, transcendence,* and other existential hypotheses.

MAYBERG, HELEN Mayberg is best known for her work in the field of functional brain imagery in mood disorders.

McCLELLAND, DAVID C. (1917–1998) McClelland developed a method of measuring human needs through content analysis of imaginative thought.

McDOUGALL, WILLIAM (1871–1938) McDougall described an instinct as having three aspects: (1) a predisposition to notice certain stimuli, (2) a predisposition to make movements toward a goal, and (3) an emotional core.

McEWEN, BRUCE S. (b. 1938) McEwen studies environmentally regulated, variable gene expression in the brain mediated by circulating steroid hormones and endogenous neurotransmitters in relation to brain sexual differentiation and the actions of sex, stress, and thyroid hormones on the adult brain.

McGAUGH, JAMES L. (b. 1931) McGaugh's research has revealed that memory consolidation is influenced by drugs affecting several neuromodulatory and neurotransmitter systems. Other findings indicate that adrenal stress hormones modulate consolidation, and that these effects are mediated by noradrenergic activation of the amygdala.

McGUIRE, WILLIAM J. (b. 1925) McGuire developed a probability model of thought systems and has also worked on theories regarding the self-concept, attitude change, and personality correlates of persuasion. He also contributed to the psychology of science by developing a "perspectivist" approach describing how researchers do and should develop psychological knowledge.

McKEACHIE, WILBERT J. (b. 1921) Much of McKeachie's research has been concerned with attribute treatment interactions, particularly with respect to those teaching variables interacting with student motivation, such as test anxiety.

MEAD, GEORGE H. (1863–1931) For Mead, the self was an object of awareness rather than a system of processes. At birth there is no self because a person cannot enter one's own experiences directly.

MEAD, MARGARET (1901–1978) Mead pioneered in research methods that helped to turn cultural anthropology into major science. Throughout her career she promoted the importance of environmental influences, women's rights, and racial harmony.

MEEHL, PAUL E. (1920–2003) Meehl's monograph, *Clinical versus Statistical Prediction,* aroused wide interest (and dissent) and is considered a classic work in psychology. He is considered one of the intellectual giants of 20th-century psychology.

MELZACK, RONALD Along with Patrick Wall, Melzack developed the innovative gate control theory of pain. He also helped reveal the neural areas and pharmacological mechanisms involved in pain. Melzack developed the McGill Pain Questionnaire to obtain measures of the multiple dimensions of subjective pain experience, and he later developed the neuromatrix model of brain function, which plays a major role in explaining phantom limb pain.

MERLEAU-PONTY, MAURICE (1907–1961) Merleau-Ponty's primary concern was an understanding of the relationship between consciousness and nature. For him, *nature* referred to external events in their causal relationships. Consciousness, however, was not subject to causality.

MESMER, FRANZ ANTON (1734–1815) Mesmer is commonly recognized as the founding father of modern hypnosis. He attempted to build on the rock of Newtonian ideas to find some basis for understanding human illness and cures.

MEYER, ADOLF (1866–1950) Meyer is best known for his theory of psychobiology, which emphasized the importance of a biographical study for understanding all aspects of an individual's personality.

MILGRAM, STANLEY (1933–1984) Milgram's best-known studies were on the dynamics of obedience to authority. As a result, he found an unexpectedly high rate of obedience. His obedience work has become one of the best-known pieces of research in the social sciences.

MILL, JOHN STUART (1806–1873) Mill believed that a combination of mental events resulted in something totally new that was not present in the original experiences, a notion that became identified as *mental chemistry.*

MILLER, GEORGE A. (b. 1920) Miller was the first to demonstrate trial-and-error learning motivated by electrical stimulation of the brain.

MILLER, NEAL E. (1909–2002) Miller pioneered the application of learning theory to behavioral therapy and the use of chemical and electrical stimulation to analyze the brain's mechanisms of behavior, homeostasis, and reinforcement. His work with animals profoundly aroused the interest and focus of the scientific community in the field of biofeedback.

MILNER, BRENDA (b. 1918) Milner's work has involved the intellectual effects of temporal lobe damage in humans. She has also explored memory disorders and the effect of brain lesions or injury on cerebral organizations.

MISCHEL, WALTER (b. 1930) The model of personality developed by Mischel incorporates social, cognitive, and emotional processes and variables into the conceptualization of personality. His model takes systematic account of the role of the situation in interaction with the characteristics of the person, into the expressions of behavioral consistency.

MISIAK, HENRYK (1911–1992) Misiak's experimental research focused on the perception of intermittent light, particularly on various parameters and applications of critical flicker frequency (CFF).

MONTESSORI, MARIA (1870–1952) Montessori used her scientific background to create universal principles and special methods and materials for a new pedagogy.

MORENO, JACOB L. (1892–1974) Moreno developed the technique of psychodrama, a method of psychotherapy that depends on dramatic role playing.

MORGAN, CONWAY LLOYD (1852–1936) Morgan is best known for the Lloyd Morgan's Canon, an application of the Law of Parsimony to an explanation of animal behavior.

MORITA, SHOMA (1874–1938) Morita developed a new form of psychotherapy, generally known as Morita Therapy, that combined psychotherapy and Zen Buddhism. To gain insight, the patient must be in harmony with the universe.

MOWRER, O. HOBART (1907–1982) Mowrer's best-known and probably most enduring practical contribution is a means of treating nocturnal enuresis known as the bell-and-pad method. His more substantive contribution was his two-factor theory of learning, language, and interpersonal psychology.

MÜLLER, JOHANNES (1801–1858) Müller is best known for his doctrine of the "specific energies of nerves," which states that, regardless of how it is stimulated, each sensory nerve will lead to only one kind of sensation.

MÜNSTERBERG, HUGO (1863–1916) Münsterberg exposed the fraudulence of popular mystics and occult figures, and he generally applied psychology to everyday life.

MURPHY, GARDNER (1895–1979) Murphy's biosocial approach to psychology was recognized as one of the most vital and influential movements in the field.

MURRAY, HENRY A. (1893–1988) Murray developed his taxonomy of needs to characterize people's directions in their lives and activities. Thus, he developed a systematic and dynamic approach to personality.

MUSSEN, PAUL HENRY (1922–2000) Mussen is best known for his research and writings in developmental psychology. His research involved the study of developmental processes in preschool children, generosity in children of nursery school age, and the impact of television cartoons on children's aggressive behavior.

MYASISHCHEV, VLADIMIR N. (1893–1973) Myasishchev suggested that conditioned reflexes might not be an adequate explanation of human motor behavior.

NAKANISHI, SHIGETADA (b. 1942) Nakanishi and colleagues developed a novel cloning strategy to isolate receptors and ion channels by combining electrophysiology and the Xenopus oocyte expression system, and they applied this strategy to the molecular cloning of glutamate receptors. Nakanishi and colleagues also elucidated the molecular nature of neuropeptide and vasoactive peptide receptors.

NATHAN, PETER E. (b. 1935) Nathan has extensively researched basic psychosocial variables associated with alcoholism. He has investigated such diverse issues as alcohol abuse and dependence, syndromal diagnosis, and psychotherapy outcomes.

NEISSER, ULRIC (b. 1928) Neisser is best known for three books: *Cognitive Psychology,* which helped to establish that field; *Cognition and Reality,* which attempted to reorient it; and *Memory Observed: Remembering in Natural Contexts,* which introduced the ecological approach to the study of memory.

NEMEROFF, CHARLES B. (b. 1949) Nemeroff's research has concentrated on the biological bases of the major neuropsychiatric disorders, including affective disorders, Alzheimer's disease, Schizophrenia, and anxiety disorders.

NESTLER, ERIC J. (b. 1954) The goal of Nestler's research is to better understand how the brain adapts to repeated perturbations under both normal and pathological conditions. His laboratory has discovered several adaptations that occur in the brain in response to chronic drug exposure and has provided evidence that these adaptations are responsible for certain behavioral features of addiction.

NETTER, PETRA (b. 1937) Netter initiated research activities in the field of sensory suggestibility in relation to pain tolerance and placebo response.

NEWCOMB, THEODORE M. (1903–1984) Newcomb was among the first psychologists to identify himself with social psychology. He showed that an individual's characteristics and group memberships interacted to influence attitude changes after leaving college.

NIETZSCHE, FRIEDRICH WILHELM (1844–1900) Nietzsche was convinced that psychology should consider the will to power as the primary human motive.

NOIZET, GEORGES (b. 1925) Noizet's main work deals with strategies in the comprehension of utterances and with evaluative judgments.

NÚÑEZ, RAFAEL (b. 1921) Núñez is best known for his research on Mexican personality characteristics. He

searched for methods of understanding the psychological problems of the lower economic classes in Latin America.

NUTTIN, JOSEPH R. (1909–1988) Nuttin was one of the first psychologists to formulate an integrated cognitive theory of human selective learning. He is also known for his theory of human motivation in terms of behavioral relations required for optimal functioning.

O'BRIEN, CHARLES (b. 1937) O'Brien is best known for his studies on the causes and treatment of substance disorders.

OKONJI, MICHAEL OGBOLU (1936–1975) Okonji conducted research focused on child rearing, especially the relationship between the field-independence perspective of Herman Witkin and the intellectual perspective of Jean Piaget.

OLDS, JAMES (1922–1976) Olds and Milner were able, by chance, to produce pleasurable effects by electrically stimulating the brain. This led them to assume that a "reward mechanism" exists in the brain and serves as a motivational apparatus.

O'LEARY, K. DANIEL (b. 1940) O'Leary has investigated behavioral procedures for reducing aggressive and hyperactive behavior in children, the ways in which marital discord affects children, and risk factors and treatments for men and women in physically aggressive relationships. He also helped develop a marital therapy treatment for individuals experiencing marital discord and depression.

OSGOOD, CHARLES EGERTON (1916–1991) Osgood's experimental research has centered around the role of meaning within the context of learning theory. He developed the Semantic Differential Method while searching for a tool to quantify meaning.

OTIS, ARTHUR SINTON (1886–1964) Otis developed the Otis Group Intelligence Scale, which incorporated, for the first time, completely objective scoring and multiple-choice items, the keys to group testing and administration by minimally trained personnel.

OVERMEIER, JAMES BRUCE (b. 1938) Overmeier's research spans specialties of learning, memory, stress, psychosomatic disorders, and their biological substrates. This research has been carried out with a variety of species of laboratory animals and with human client volunteers with Down syndrome, Korsakoff's syndrome, or Alzheimer's disease.

PARAMESWARAN, E. G. (b. 1935) Parameswaran, known for his approach to the study of personality, is a pioneering researcher in the area of developmental psychology in India.

PATTERSON, GERALD R. Patterson and his colleagues have made numerous contributions to understanding of child and adolescent aggression. He has developed and evaluated behavioral interventions to prevent and treat aggression.

PAUL, GORDON (b. 1935) Paul's work helped to form the foundation for the evidence-based practice movement in psychology. His clinical research demonstrated the utility of psychosocial principles for understanding and cost-effective nonpharmacological treatment of problems ranging from anxiety disorders to Schizophrenia.

PAVLOV, IVAN PETROVICH (1849–1936) Pavlov's methodology and his greatest scientific achievement was conditioning, a technique that significantly influenced the development of psychology.

PEARSON, KARL (1857–1936) Pearson contributed to the development of the biological, behavioral, and social sciences. His application of mathematical and statistical methods ranks among the great achievements of science. He developed widely used correlation statistics.

PECJAK, VID (b. 1929) Pecjak studied concepts and conceptual interrelations and symbols and their cultural dependence. He found that some symbols are universal, whereas others are unique to individual cultures.

PEDERSEN, PAUL B. (b. 1936) Pedersen conducted research in Indonesia, Malaysia, and Taiwan that emphasized interdisciplinary area studies, with special attention to core values as they are influenced by cultural perspectives.

PEIRCE, CHARLES SANDERS (1839–1914) Peirce held that the domain of knowledge could be so characterized that general assertions could be proven true of all knowledge and that all knowledge depended on logic that made such a characterization possible.

PENFIELD, WILBER GRAVES (1891–1976) Among Penfield's contributions were the development of neurosurgical treatment of certain forms of epilepsy and the discovery that electric stimulation of certain parts of the cortex can evoke vivid memories of past life experiences.

PERL, EDWARD ROY (b. 1926) Perl's first studies in neuroscience utilized electroencephalography and responses of the cerebral cortex to sensory input. Subsequently, his work focused on reflex and somatosensory mechanisms of the mammalian spinal cord. He is widely recognized for pioneer efforts in the documentation of the existence and function of nociceptors.

PERLOFF, ROBERT (b. 1921) Perloff has contributed to psychology through his research on consumer behavior and evaluation studies relating to mental health and educational programs.

PERLS, FREDERICK (FRITZ) (1893–1970) Perls's major contribution to psychology was the development of

a new method of psychotherapy, which he named Gestalt therapy, an outgrowth and a rejection of psychoanalysis.

PETERSEN, ANNE C. (b. 1944) Petersen's research interests have included adolescent biopsychosocial development and mental health. She was a leader in demonstrating scientifically the importance of considering the influence of biological change on psychological and social changes in adolescence. She has also investigated the increased risk for depression among adolescent girls.

PETERSON, DONALD R. (b. 1923) Peterson's research has involved topics such as the diagnosis of subclinical schizophrenia, children's behavior disorders, juvenile delinquency, parent-child relationships, and the interaction process in marital relationships. In addition, his trait-based research contributed to the "big five" conceptions of personality structure that were later commonly accepted.

PFAFFMAN, CARL (1913–1994) Pfaffman conducted research on taste and other chemical senses and attempted to find basic relationships between the physiological and psychological aspects of organisms.

PFLÜGER, EDUARD FRIEDRICH WILHELM (1829–1910) Pflüger's research involved studies of the nervous system. He became involved in the controversy over whether reflexes are conscious or unconscious.

PIAGET, JEAN (1896–1980) Piaget studied the relationships formed between the individual knower and the world he or she endeavors to know. His two most important concepts of genetic epistemology are *functional invariants* and *structures*.

PIERON, HENRI (1881–1964) Pieron's work focused on psychophysiology. During an early part of his career, he studied the mechanisms of sleep in animals, but the psychophysiology of sensations constituted the center of his scientific work.

PILLSBURY, WALTER BOWERS (1872–1960) Pillsbury is probably best known as an historian of psychology. His *History of Psychology* details the growth of psychology from philosophy.

PINEL, PHILIPPE (1745–1856) Pinel made a plea for more humane treatment of the insane, who, at that time, were regarded by many as wicked and possessed by demons. He offered an alternative explanation that related disturbed behavior to brain malfunctions.

PINILLOS, JOSÉ (b. 1919) Pinillos is best known for his work on social attitudes and political stereotypes and for his analysis of the F-scale.

PIZZAMIGLIO, LUIGI (b. 1937) Pizzamiglio contributed to the introduction of psycholinguistic models to explain aphasia and hemispheric dominance for cognitive abilities.

PLATO (427–347 B.C.) Plato's influence on Western thought has been inestimable, extending to metaphysics, epistemology, ethics, politics, mathematics, and several branches of natural science.

PLOTINUS (204–270 A.D.) Plotinus described the soul as a unitary entity, completely separate from the body, that is indestructible and immortal. He believed the soul's relation to the body was one of collateral existence, not mixing with the body but dwelling beside it, thus having an existence of its own.

PONZO, MARIO (1882–1960) Ponzo's research was in general and experimental psychology, including the histology and psychophysiology of taste, and tactile and thermic stimulus localization in different regions of the skin.

PORTEUS, STANLEY DAVID (1883–1972) Porteus began his best-known work in psychology, his Maze Test, as a supplement to Henry H. Goddard's 1909 translation of Alfred Binet's intelligence tests that would avoid the culture factor.

PRIBRAM, KARL H. (b. 1919) Pribram has investigated mind-brain problems with a focus on their philosophical implications, drawing on laboratory data to support his premises.

PRINCE, MORTON (1854–1929) Prince described the biography of a multiple personality who had three distinct personalities that alternated with each other, characterized as the saint, the devil, and the woman. Two of the personalities had no knowledge of the others.

PURKINJE, JAN EVANGELISTA (1787–1869) An extensive researcher of sensory elements in the phenomenological tradition, Purkinje described how colors emerged from darkness at dawn.

QUAY, HERBERT C. (b. 1927) Quay's major research contributions include his taxonomic work in both juvenile and adult offenders, his early work in the education of children with behavior disorders, and his later work in the experimental psychopathology of childhood and the adolescent disorders.

QUETELET, LAMBERT ADOLPHE JACQUES (1796–1874) Quetelet extended the notion of the normal distribution as being the true state of affairs rather than simply measurement error.

RACHMAN, STANLEY J. (b. 1934) Rachman, working with Eysenck, was responsible for much of the early work on behavior therapy in England. He was the founding editor of *Behavior Research and Therapy.*

RAIMY, VICTOR (1913–1987) Raimy proposed that changes in the self-concept would be used to chart the course of psychotherapy as well as general changes in personality. In his theory, the self-concept is seen as a guide or map that persons consult when faced with choices.

RAINA, MAHARAI K. (b. 1943) Raina has been involved in research on the National Talent Search Scheme in India. He has concentrated on longitudinal studies of the talented and the role of creativity in the talent search.

RAMON Y CAJAL, SANTIAGO (1832–1934) Ramon y Cajal is called the father of present-day physiological psychology. His techniques for tracing neurons histologically remain a basic approach to physiological psychology.

RANK, OTTO (1884–1939) Rank sought to develop an alternative scientific approach built on the person as both a voluntary interpreter of meaning and an initiator of action. His earlier conception of the birth trauma was largely replaced by more complex ideas. He also rejected the aim, shared by Freud and most of academic psychology, of mechanistic explanation of human behavior or experience with a cause-effect paradigm.

RAO, K. RAMAKRISHNA (b. 1932) Rao's contributions to psychology, both theoretical and experimental, focus mainly on aspects such as psi, which receive little attention in conventional psychology.

RATH, RADHANATH (b. 1920) After his early specialization in psychophysics, Rath turned to social psychology. While involved in the reorientation of primary school education and textbooks he performed intensive research in the area of early education.

RAVIV, AMIRAM (b. 1939) Raviv's research areas include prosocial behavior, pupils' attributions of success and failure, social climate in various settings, and issues related to the role of school psychologists.

RAZRAN, GREGORY (1901–1973) Razran conducted extensive research in the area of classical conditioning by relating the various types of learning to levels of evolutionary development.

REICH, WILHELM (1897–1957) Reich parted from psychoanalysis as his pursuits led him into realms the analysts could not or would not follow. For him, emotions came to mean the manifestation of a tangible, demonstrable biological energy (*orgone*).

REID, THOMAS (1710–1796) Reid proposed that not only did people possess minds, but also any individual mind knew more than it possessed. He also proposed faculty psychology.

REIK, THEODOR (1888–1969) Although a believer in many psychoanalytical concepts, Reik disagreed with Freud over certain matters of love and sex. He believed that true romantic love has little to do with sex—that it is felt most strongly when the loved one is absent.

RESCORLA, ROBERT A. (b. 1940) Rescorla's early work led to the development of the "truly random control" procedure, together with the contingency view of conditioning. He also helped form an influential theory of elementary learning processes, the Rescorla-Wagner model, which continues to be one of the touchstones for thinking about Pavlovian conditioning.

RESNICK, ROBERT J. (b. 1940) Resnick's clinical and research interests were attention-deficit disorders. He filed the landmark "Virginia Blues" litigation establishing the autonomous practice of psychology.

REUCHLIN, MAURICE (b. 1920) Reuchlin has asserted that, in research, the content of the data and the context of the research, as well as statistical findings, must be considered.

REYKOWSKI, JANUSZ (b. 1929) Reykowski is best known for developing a theory of intrinsic motivation applied to prosocial behavior.

RHINE, JOSEPH BANKS (1895–1980) Rhine, considered the father of experimental parapsychology, spent over 50 years in active research that brought psychic research from the closed séance rooms of mediums into open laboratories of scientists.

RIBES-IÑESTA, EMILIO (b. 1944) Partly responsible for the introduction of experimental psychology into Mexico, Ribes-Iñesta contributed to the development of the first professional and graduate research programs on behavior modification and behavior analysis.

RIBOT, THEODULE (1839–1916) Together with Alfred Binet and Pierre Janet, Ribot was a founder of modern French psychology. He stressed motivational forces in personality development, which resulted in what we today would call a dynamic psychology.

RICHTER, CURT PAUL (1894–1988) Richter's research included such areas as spontaneous behavior in rats, energy biological clocks, galvanic skin response, and rhythms, as well as nutrition and self-selection of diets in rats.

RIVERS, WILLIAM HALSE (1864–1922) Rivers became interested in neurology and medical psychology during World War I. With Elliot Smith and T. H. Pear, he was the first to recognize "shell shock" as a distinct clinical entity.

ROGERS, CARL RANSOM (1902–1987) Rogers developed a psychotherapeutic system, which during the 1950–1960 era was second in popularity only to that of Freud, in which the therapist acts as a facilitator. In everyday terms his form of therapy is called *nondirective.*

ROKEACH, MILTON (1918–1988) What people believe, why they believe, and what difference it makes are the recurring themes that preoccupied Rokeach during his research career. His work on human values is already considered a classic book.

ROMANES, GEORGE JOHN (1848–1894) Romanes, a student of behavior, chose to use the anecdotal method

that he culled from both the scientific and popular literature. He criticized the tendency to attribute human characteristics, such as insight, to animals.

RORSCHACH, HERMANN (1884–1922) Rorschach extended the inkblot technique to measure the entire personality.

ROSENZWEIG, SAUL (b. 1907) Rosenzweig is best known for his studies and theories of frustration and aggression. He has also studied tolerance for frustration and has noted that the spoiled child is ill equipped to handle frustration.

ROT, NIKOLA (b. 1910) Three areas are central in Rot's empirical research: psychological characteristics of judgments, attitudes, and problems connected to self-management.

ROTTER, JULIAN B. (b. 1916) Rotter's major contribution has been the development of social learning theory (SLT), in which he tried to integrate the two great traditions in psychology: the stimulus-response (or reinforcement) theories and cognitive (or field) theories.

ROYCE, JOSEPH R. (1921–1989) Royce's major experimental research focused on determining the gene correlates of factors of emotion.

ROYCE, JOSIAH (1855–1916) Royce taught that truth could be proven, that an absolute mind exists, and that human beings can grasp truth.

RUBIN, EDGAR (1886–1951) Rubin is best known for his dissertation on the figure/ground distinction. Under some circumstances, figure and ground can reverse.

RUBINSTEIN, SERGEI LEONIDOVICH (1889–1960) Rubinstein formulated these principles of Soviet psychology: Mind is a function of matter, and the human psyche is a function of historical evolution, the unity of consciousness, and the unity of theory and practice.

RUSH, JOHN A. (b. 1942) Rush has conducted clinical investigations that span both biological and psychosocial issues in mood disorders in adults, children, and adolescents. His research efforts contributed to the development of effective pharmacological and cognitive-behavioral therapies for depressed patients and those with bipolar disorders.

RUSSELL, ROGER W. (1914–1998) Russell was one of the first to search for neurochemical mechanisms underlying normal and abnormal behavior.

RUTHERFORD, WILLIAM (1839–1899) Rutherford is known in psychology chiefly for his 1886 "Telephone Theory" of hearing.

RUTTER, MICHAEL (b. 1933) Perhaps the leading child psychiatrist in the world, Rutter wrote about and conducted research on numerous child disorders.

SAKEL, MANFRED (1900–1957) Sakel is primarily known for his discovery of the insulin coma treatment for Schizophrenia.

SAPOLSKY, ROBERT (b. 1957) Sapolsky has examined the cellular and molecular mechanisms underlying glucocorticoid-induced hippocampal neurotoxicity and its relevance to hippocampal damage during aging. Another line of Sapolsky's research involves examining relationships among social rank, personality, and patterns of stress-related disease in wild baboons.

SALTER, ANDREW (1914–1996) Salter's *Conditioned Reflex Therapy* was a major contribution to the founding of behavior therapy; he was also a cofounder of the Association for the Advancement of Behavior Therapy. His *Case against Psychoanalysis* offended many in the psychiatric establishment.

SANFORD, EDMUND CLARK (1869–1924) As an innovator of psychological apparatus, Sanford developed the vernier pendulum chronoscope, which once was a standard instrument for studying reaction time.

SAPIR, EDWARD (1884–1939) Sapir's study of language in Native American tribes was an early contribution to linguistic anthropology.

SCARR, SANDRA WOOD (b. 1936) Scarr explored genetic variability in human behaviors through twin, adoption, and intervention studies.

SCHACHTER, STANLEY (1922–1997) Schachter developed a cognitive theory of emotion in which he established that people cannot discriminate one emotion from another unless they have some cognitive indication of to what their feelings relate.

SCHAIE, K. WARNER (b. 1928) Schaie's principal contributions are long-term longitudinal research on adult intellectual development and study in the area of developmental research methodology.

SCHATZBERG, ALAN (b. 1944) Schatzberg has provided an enhanced understanding of the biology of psychotic depression.

SCHOPENHAUER, ARTHUR (1788–1860) Schopenhauer stressed the redemption of the soul from its sensual bonds. According to him, human beings have an obligation to sensual things, but the final goal is to rise above the senses into the bosom of a peaceful Nirvana.

SCHUMANN, FRIEDRICH (1863–1940) Schumann studied many visual forms and illusions without finding any necessity to appeal to the concept of form-quality. Instead, this could be accounted for by the laws of attention as well as eye movements.

SCOTT, WALTER DILL (1869–1955) Scott transferred his psychological insights into the world of work and in-

troduced the business uses of psychology into advertising, selling, and consumer behavior. Thus, he created a new field-industrial psychology.

SCRIPTURE, EDWARD WHEELER (1864–1945) Scripture coined the term *armchair psychology* to describe those psychologies that state theories and speculations without experimental verification.

SEARS, ROBERT R. (1908–1989) Sears's initial interests in physiological psychology shifted to personality and motivation. He performed numerous verification studies on psychoanalytic concepts.

SEASHORE, CARL EMIL (1866–1949) For many years, Seashore devoted his experimental efforts to the study of music psychology. His thesis was that musical talent consisted of many different capacities.

SECHENOV, IVAN MIKHAILOVICH (1829–1905) The founder of Russian physiology, Sechenov was a mentor to Ivan Pavlov and instrumental in bringing psychology and science together.

SEGUIN, EDOUARD (1812–1880) Seguin originated sense and muscle training techniques whereby children with mental retardation were given intensive exercise in sensory discriminations and in the development of muscle control.

SELIGMAN, MARTIN E. P. (b. 1942) Seligman reformulated the learned helplessness model, claiming that attributions governed the expression of helplessness. More recently, he has developed and implemented applications of "Positive Psychology."

SELYE, HANS (1907–1982) Selye formulated a code of behavior based on the laws that govern the body's stress resistance in dealing with personal, interpersonal, and group problems.

SERPELL, ROBERT (b. 1944) Serpell's research centered on the application of attention theory to various aspects of child development, notably perceptual errors on Western intelligence tests and second-language learning in Zambia.

SHAFFER, DAVID A British psychiatrist, Shaffer has studied suicide as it relates to mood disorders and externalizing behaviors among adolescents.

SHAKOW, DAVID (1901–1982) Shakow is best known for his role in the development and descriptions of models for training in clinical psychology. The "Shakow Report" set the training model as a Ph.D. according to the "Boulder Model of Combined Training in Science and Practice."

SHERIF, CAROLYN (1922–1982) Sherif collaborated with her husband Muzafer Sherif in a series of important studies regarding changing racial attitudes. She went on to make major contributions to social rejection theory and the roles of women in psychology. She was among the "four mothers" of psychology.

SHERIF, MUZAFER (1906–1988) Sherif initiated a series of naturalistic experiments on group formation, intergroup conflict, and cooperation.

SHELDON, WILLIAM HERBERT (1899–1977) Sheldon developed an empirical basis for the structural theory of personality first suggested by Hippocrates and Galen. Sheldon refined what were essentially Kretschmer's three basic body types.

SHERRINGTON, CHARLES SCOTT (1857–1952) Sherrington published studies on color vision and flicker and wrote on the tactual and muscular senses. He introduced the terms *interoceptor, exteroceptor,* and *proprioceptor.* Wolpe based much of his work on relaxation training on Sherrington's ideas, even though they were later called into question.

SHNEIDMAN, EDWIN S. (b. 1918) Shneidman is a suicidologist and thanatologist who has researched death and suicide.

SIGUAN, MIGUEL (b. 1918) Siguan has been a pioneer in the field of infant language, attempting to explain the origins of verbal language as arising from nonverbal communication.

SIMON, HERBERT A. (1916–2001) Simon has pioneered in creating information-processing psychology and has been active in the fields of mathematical economics and organization theory.

SINGER, GEORGE (b. 1922) Singer's major contributions to psychological research are in perception: eating, drinking, and drug intake behaviors, and the application of biochemical methods to the assessment of stress programs.

SINGH, SHEO DAN (1932–1979) Singh established India's first Primate Research Laboratory. His major areas of interest were the impact of urban conditions on the development of social, emotional, and cognitive behavior and the brain chemistry of rhesus monkeys.

SKINNER, BURRHUS FREDERICK (B. F.) (1904–1990) Skinner took a completely objective approach to psychology. He contended that learning occurs as a result of some kind of reinforcement, either positive or negative.

SMITH, M. BREWSTER (b. 1919) Smith studied anti-Semitism, race prejudice, and moral judgment in the student activists of the 1960s. He sought to link the complementarities of scientific and humanistic psychology by focusing on selfhood or personality.

SNYDER, SOLOMON H. (b. 1938) Snyder and colleagues were the first to identify opiate receptors in the brain, a discovery that opened the door to an increased

understanding of the actions of addictive drugs. In addition, to challenge the notion that brain cells could not reproduce, Snyder and colleagues concocted a growth medium in which a colony of neurons functioned normally and also multiplied.

SOBELL, LINDA (b. 1947) Sobell's work has focused on problems with alcohol consumption. Her early work with Mark Sobell triggered a major controversy on "controlled drinking."

SOLOMON, RICHARD LESTER (1919–1992) Solomon's research involved numerous areas of experimental psychology. Of particular importance were his various studies of traumatic avoidance learning in dogs. In these studies, he explored many parameters of the problem, some of which later became known as "learned helplessness."

SPEARMAN, CHARLES EDWARD (1863–1945) Spearman discovered that individual differences on all tests of mental abilities are positively intercorrelated in representative samples of the general population.

SPENCE, JANET TAYLOR (b. 1923) Spence developed the Manifest Anxiety Scale as a vehicle for testing her and Kenneth Spence's theory about the interactions between task characteristics and drive or arousal level in determining task performance. In the later years of her career, she focused on masculinity and femininity and how they related to performance.

SPENCE, KENNETH W. (1907–1967) In the philosophy of science and the tenets of logical empiricism, Spence sought the bases on which psychology could proceed as an objective, empirical science.

SPENCER, HERBERT (1820–1903) Spencer considered associationism the most binding psychological principle. Along with his contemporary, Alexander Bain, he brought the entire movement of British associationism to an end.

SPERRY, ROGER WOLCOTT (1913–1994) Sperry's finding, the split-brain phenomenon, created considerable discussion among neuropsychologists and led to the dual personality theory.

SPIELBERGER, CHARLES (b. 1927) Spielberger's research interests have focused on personality and learning, stress, anxiety, and curiosity, and the experience, expression, and control of anger. With adaptations in 52 languages and dialects, his State-Trait Anxiety Inventory is the standard international self-report measure of anxiety.

SPINOZA, BENEDICT BARUCH (1632–1677) Spinoza's philosophy was rationalistic and deductive. Human beings, as a manifestation of God, reflect the psychophysical parallelism that prevails throughout the universe. People have two aspects, mind and body, which are basically one.

SPRANGER, EDUARD (1882–1963) Spranger identified six types of people in terms of their life goals and values that operated apart from any biological drives or needs.

SPURZHEIM, JOHANN GASPER (1776–1832) Spurzheim, a phrenologist, identified 37 faculties of the mind, each related to a specific cortical location. His grouping of the faculties into mental, motive, and vital types anticipated Sheldon's somatotypes.

SQUIRE, LARRY R. (b. 1941) Squire's studies of human memory provided some of the first evidence for the biological reality of multiple memory systems. In addition, the work of Squire and colleagues led to the establishment of an animal model of human amnesia in the monkey and eventually to the identification of the anatomical components of the medial temporal lobe memory system.

STEINER, RUDOLF (1861–1925) Steiner founded the first Waldorf School, now the largest nonsectarian private school system in the world. He taught that the development of humankind's intellectual and spiritual faculties could lead to a "spiritual science."

STEKEL, WILHELM (1868–1940) Stekel stressed the teaching role of the analyst and saw the therapeutic relationship as an active partnership. He believed that the goals of the patient are important and that the patient should be led to distinguish between genuine and false goals.

STEVENS, CHARLES F. (b. 1934) Stevens's research centers on mechanisms responsible for synaptic transmission. He has investigated various mechanisms used by the central nervous system for the short- and long-term regulation of synaptic strength, and he has used a combination of methods to elucidate the molecular basis of neurotransmitter release at synapses.

STEVENS, STANLEY SMITH (1906–1973) Stevens found that physical continua generally conform to a psychophysical power law rather than Gustav Fechner's logarithmic law.

STOUT, GEORGE FREDERICK (1860–1944) Stout rejected mental chemistry and criticized associationists for confusing the "presented whole" with the "sum of its presented components." Thus, Stout anticipated the Gestalt cry that "the whole is greater than the sum of its parts."

STRATTON, GEORGE MALCOLM (1865–1957) Stratton wore special lenses that reversed the field of vision, up for down and right for left, during his waking hours for 8 consecutive days. After 3 days he was able to make relatively automatic and skilled movements and adjust to seeing an inverted world.

STRICKLAND, BONNIE (b. 1936) Strickland's research of students involved in the civil rights movement

demonstrated that internal locus of control beliefs are related to direct social action. She has also investigated the mental health status of lesbians and gay men, the effects of discrimination on children's development, and various factors leading to the greater incidence of depression among women.

STRONG, EDWARD KELLOGG, JR. (1884–1963) Strong spent most of his career measuring vocational interests. His later publications dealt with the variation of interests over time, including a large group studied 18 years after completing college.

STRUPP, HANS H. (b. 1921) Strupp viewed the nature of the psychotherapist's influence and the patient's susceptibility to that influence as one of the core problems in psychotherapy research. He conducted several studies on verbal psychotherapy.

STUMPF, CARL (1848–1946) Stumpf's *Tonpsychologie* was the first work on the psychology of music. One of the most important aspects of this work was his theory of consonance and dissonance in music.

STUNKARD, ALBERT J. (b. 1922) Stunkard conducted extensive research on eating patterns and hunger with animals. He subsequently has completed numerous investigations of the effectiveness of various behaviorally based weight loss programs.

SULLIVAN, ARTHUR M. (b. 1932) Sullivan investigated teaching and learning at the remedial level as well as at the first- and second-year university level. The teaching and remedial programs that he devised resulted in dramatic increases in academic success.

SULLIVAN, HARRY STACK (1892–1949) Not only is personality couched in interpersonal relations, Sullivan believed, but also the patient-therapist interpersonal relationship is critical for successful therapy. His model served as the basis of Klerman and Weissman's *Interpersonal Psychotherapy.*

SUNDBERG, NORMAN D. (b. 1922) Sundberg emphasizes both the "horizontal" and the "vertical": "horizontal" in the sense of knowledge across cultures, communities, and applied activities, and "vertical" in the sense of an appreciation of time, of the history and future of the life span.

SUPER, DONALD E. (1910–1994) Super is most often associated with career development theory and its applications. After contributing first to the applications of differential psychology to vocational guidance and personnel selection and classification, he shifted his attention to developmental approaches to vocational choice and development.

SZASZ, THOMAS S. (b. 1920) Szasz is best known for his proposition that mental illness is a myth and for his uncompromising opposition to psychiatric coercions and excuses.

SZEWCZUK, WLODZIMIERZ L. (b. 1913) Szewczuk found three necessary conditions for any memorization: an active attitude, association with earlier experience, and association with emotional reactions.

TAYLOR, FREDERICK WINSLOW (1856–1915) Taylor founded the area of industrial efficiency. He prescribed the time study with standardized tools and procedures organized by a planning department. Equipment was redesigned to be consonant with human abilities.

TEPLOV, BORIS MIKHAILOVICH (1886–1965) Teplov related individual differences to the nervous system, stressing the importance of involuntary reflexes in a manner first studied by Ivan Pavlov.

TERMAN, LEWIS MADISON (1877–1956) Terman's major research contribution to American psychology was his work in intelligence testing and his evaluation of gifted persons.

THOMAS AQUINAS (1225–1274) In his *Summa Theologica,* Thomas Aquinas stated that some things can be known by faith only, others by reason only, and still others by both revelation and rational proof. As humans seek truth, they are also seeking the final good.

THOMPSON, RICHARD F. (b. 1930) In collaboration with W. Alden Spencer, Thompson developed criteria for habituation and evidence that the basic process is a form of synaptic depression that occurs presynaptically.

THOMSON, GODFREY H. (1881–1955) Thomson regarded the mind as comprising a very large number of "bonds," similar to Thorndike's "connections." Any mental act would draw on a sample of bonds, while other acts would draw on some of the same and some that were different.

THORNDIKE, EDWARD LEE (1874–1949) Thorndike taught that psychologists should study behavior, not mental elements or conscious experience. He did fundamental work in understanding learning and also preceded Pavlov's *law of reinforcement* with his *law of effect.*

THURSTONE, LOUIS LEON (1887–1955) Thurstone is best known for his contributions to factor analysis. His multiple factor theory has endured; however, with the advent of electronic computers, his centroid method of factor extraction has been replaced by more exact methods.

TILLICH, PAUL (1886–1965) Tillich believed that religious questions arise from human situations and therefore are practical and not primarily theoretical. He was strongly influenced by existentialism.

TINBERGEN, NIKOLAAS (1907–1988) Many of Tinbergen's works have become classics in both psychology

and biology, including his work on courting behavior in sticklebacks, orienting behavior in wasps, and the behavior of grayling butterflies.

TITCHENER, EDWARD BRADFORD (1867–1927) Titchener brought structuralism to the United States from Wundt's laboratory in Leipzig. He was a dominant figure in the early years of American psychology.

TOLMAN, EDWARD CHASE (1886–1959) Tolman is primarily known for his theory of learning. Many psychologists consider this a cognitive field theory, although in his many experiments, primarily with the white rat, he always stressed behavior. He is usually credited with introducing the concept of the intervening variable into psychology.

TRIANDIS, HARRY C. (b. 1926) Triandis focused his work on social factors in cross-cultural research.

TULVING, ENDEL (b. 1927) Tulving has collaborated with Kanneman for much of his career, and they have made major contributions to cognitive psychology and decision theory.

TYLER, LEONA E. (1906–1993) Tyler's work focused on assessment and test construction theory.

ULLMAN, LEONARD P. (b. 1930) Studies of verbal operant conditioning led Ullman and colleagues to a direct, rather than indirect, formulation of the development, maintenance, and change of behavior. The thread in Ullman's work is that being precedes essence—that the focus of study should be overt behavior, which is observable, rather than personality, which is inferred after the fact.

UNDERWOOD, BENTON J. (1915–1994) Underwood's research efforts were devoted to the field of human learning. He explored many facets of verbal learning processes, including problems in retroactive and proactive inhibition, distributed practice, and the role of meaningfulness in associative learning, as well as a variety of variables that contribute to the degree of remembering and forgetting following verbal learning.

UZNADZE, DMITRII NIKOLAYEVICH (1886–1950) Uznadze is best known for his theory of "set" as an objective approach to the unconscious.

VAIHINGER, HANS (1852–1933) Vaihinger is known for his philosophy of "as-if": Something can work as if true even though it is false and recognized as false.

VERNON, PHILIP E. (1905–1987) Vernon conducted a series of comparative studies of abilities in different parts of the world, from Tanzania to the Arctic.

VERPLANCK, WILLIAM S. (b. 1916) Verplanck showed that successive psychological judgments are not independent of one another, as theory dictated.

VITELES, MORRIS (1898–1996) Viteles structured the field of industrial psychology as it is today. His emphasis on the need for a solid experimental basis for industrial applications helped to counter conversion of industrial psychology into industrial psychotechnology.

VYGOTSKY, LEV SEMYONOVICH (1896–1934) Vygotsky opposed the reflexology of Bekhterev, arguing that a study of mind was necessary because it distinguished humans from lower animals. However, he rejected introspection as a method.

WALKER, C. EUGENE (b. 1939) Walker's research has involved psychological testing and measurement, behavioral approaches to psychotherapy, and the effects of pornography on behavior. His interests also include hyperactive behavior in children, child abuse, and juvenile and adolescent sex offenders.

WALLON, HENRI (1879–1962) Wallon saw emotion as a physiological fact with humoral and physiological aspects, mediating between sensations and the social world.

WANG, ZHONG-MING (b. 1949) Wang has been active in the areas of reward systems design, group attributional training, high-tech innovations, judgment and decision making, and decision support systems.

WARD, JAMES (1843–1924) Even though Ward was considered by many to be a philosopher more than a psychologist, he was instrumental in establishing the first psychological laboratory at Cambridge.

WARREN, HOWARD CROSBY (1867–1934) Warren is best known as a writer and editor. He was a contributor to James Baldwin's *Dictionary of Philosophy and Psychology* and published the *Dictionary of Psychology,* which was a standard work for many years.

WASHBURN, MARGARET FLOY (1871–1939) Washburn's research included work on individual differences, color vision in animals, and aesthetic preferences by students for colors and speech sounds.

WATSON, JOHN B. (1878–1958) The founder of American behaviorism, Watson established its two tenets: psychology as an objective science and psychology as the science of behavior.

WATT, HENRY JACKSON (1879–1925) Watt's main contribution involved the study of experience as it occurred in word associations.

WEBB, WILSE BERNARD (b. 1920) Webb's research emphasized the role of individual differences and biological rhythms as determinants of sleep deprivation and performance, and also the effects of aging.

WEBER, ERNST HEINRICH (1795–1878) Weber's main research concern was in the field of sensory physiology. He found that the point of just noticeable difference bears a constant relationship to the standard. This relationship is expressed in a formula by Gustav Fechner, who identified it as Weber's law.

WECHSLER, DAVID (1896–1981) Wechsler applied his creative efforts to the development and standardization of intelligence scales that bear his name and to the substitution for Binet's Mental Age of a Deviation Quotient.

WEINBERGER, DANIEL One of the foremost investigators in the biology of Schizophrenia. More recently he has made breakthroughs on the genetic basis of emotional reactivity.

WEISS, JAY (b. 1941) One of the foremost investigators in rodent models of depression. Recently he has been working on why certain cancer patients develop depression.

WEISSMAN, MYRNA (b. 1940) Weissman's research is concerned with the epidemiology of psychiatric disorders in the community and the treatment and genetics of affective and anxiety disorders. She was a co-developer with her husband, Gerald Klerman, of interpersonal psychotherapy. She received her Ph.D. from Yale in 1974.

WERNER, HEINZ (1890–1964) Werner held that development proceeds from the undifferentiated and unarticulated to the differentiated and articulated.

WERTHEIMER, MAX (1880–1943) Wertheimer was one of the founders of Gestalt psychology. He suggested that the whole is quite *different* from the sum of clinical psychology.

WERTHEIMER, MICHAEL (b. 1927) Wertheimer's research career began with the study of sensory and perceptual processes but soon broadened to include cognition, individual differences, psycholinguistics, person perception, and eventually the history of psychology. He was the son of Max Wertheimer.

WHIPPLE, GUY MONTROSE (1876–1941) Whipple warned the American Psychological Association (APA) against charlatans and otherwise unqualified practitioners who were making inroads into clinical psychology. As a result, the APA set forth procedures for qualifying psychologists.

WHITE, ROBERT W. (1904–2001) White made a timely contribution to theory when he published *Motivation Reconsidered: The Concept of Competence,* which was soon followed by other papers on competence.

WHITE, WILLIAM ALANSON (1870–1937) White abolished the various forms of physical restraint that had been used at St. Elizabeth's hospital, replacing them with concerned humane treatment.

WICKENS, DELOS D. (1909–1988) Wickens's research activities were almost equally divided between work with human and animal subjects, a distribution expressing a bias toward addressing a basic psychology process by the most promising means.

WILCOX, RICHARD E. (b. 1947) Wilcox's work has focused on the behavioral and brain-chemistry changes induced in brain dopamine systems by dosing with dopamine agonist antiparkinson drugs, psychostimulants, and endurance-training regimens. These studies have shown that chronic stimulation of brain dopamine receptors produces adaptations in dopamine synthesis, metabolism, and release.

WILLIAMS, JOANNA P. (b. 1935) Williams has performed research on beginning reading instruction, with a focus on phonemic skills and on reading comprehension (main idea and theme identification and critical reading).

WILSON, EDWARD OSBORNE (b. 1929) Wilson's sociobiology claims that the human body with its social behavior serves to perpetuate the genes. He believes that people exist for the sake of their genes. "The organism is only DNA's way of making more DNA."

WILSON, G. TERENCE (b. 1944) Wilson's recent research has focused on eating disorders, particularly Bulimia Nervosa. He has written extensively on theories of behavior therapy. He is a former President of the Association for the Advancement of Behavior Therapy.

WITKIN, HERMAN A. (1916–1979) Witkin contributed greatly to the conceptualization of the relation between cognitive styles and personality. He believed people generally move from field dependence to field independence as they mature.

WITMER, LIGHTNER (1861–1956) Witmer established the first psychological clinic at the University of Pennsylvania. He also founded *The Psychological Clinic.* In the first issue he called for the establishment of a new helping profession, to be termed clinical psychology.

WOLFF, CHRISTIAN VON (1679–1754) Wolff stressed an active mind rather than one made up of the mere elements of experience as Locke had suggested. The mind consisted of faculties or functions such as knowledge, remembrance, feeling, and willingness.

WOLMAN, BENJAMIN B. (1908–2000) Wolman developed the interactional approach to psychotherapy, which is based on the idea that every person experiences emotional difficulties throughout life.

WOLPE, JOSEPH (1915–1997) The central point of Wolpe's research was experimental studies on the production and cure of neuroses in animals. Neuroses were produced by learning and were reversible by learning. Techniques for treating human neuroses were derived from these findings. Wolpe was one of the early founders of behavior therapy.

WOODWORTH, ROBERT SESSIONS (1869–1962) For Woodworth, the subject matter of psychology was both behavior and consciousness. He believed that behaviorists such as John Watson, who had rejected consciousness or the mind, had left out a legitimate aspect of psychology.

WUNDT, WILHELM (1832–1920) Wundt's systematic efforts established psychology as a new and recognized science in Germany during the 19th century. Using this method of introspection, students and researchers investigated the subject matter of immediate experience.

YERKES, ROBERT MEARNS (1876–1956) Yerkes invented an experimental maze to study animal learning and the evolution of intelligence through the animal species. From his experiments he formed the Yerkes-Dodson law.

YOUNG, PAUL THOMAS (1892–1978) Young is known for his studies in sound localization using a pseudophone in which the auditory inputs are reversed. He found that auditory localization is significant, particularly when the sounding object cannot be seen.

YOUNG, THOMAS (1773–1829) As a result of his interest in vision, Young became prominent in psychology. He described and measured visual astigmatism. By measuring the focal length of the eye, he demonstrated that the accommodation was attributable to the changing shape of the lens.

ZAJONC, ROBERT B. (b. 1923) Zajonc's interest has been drawn to the relationship between family structure and intellectual development. Later in his career he studied the relationship between cognition (thoughts) and emotions (feelings).

ZAPOROZHETS, ALEXANDER (1905–1981) Zaporozhets is best known for his concept of *perceptual action* and his theory of voluntary actions. He elaborated a concept of perceptual action that bound together the problems of sensorimotor skills and cognitive development.

ZEIGARNIK, BLÛMA (b. 1900) Zeigarnik is best known for her formal test of Lewin's theory that attainment of a goal or successful locomotion toward a positive valence relieves tension.

ZIGLER, EDWARD (b. 1930) Zigler's work cuts across the fields of mental retardation, mental health and psychopathology, intervention programs for economically disadvantaged children, preschool education, and out-of-home care for children of working parents. His work in mental retardation is frequently noted in efforts toward more enlightened treatment of individuals with disabilities.

ZIMBARDO, PHILIP G. (b. 1933) Zimbardo simulated prison conditions at Stanford and discovered that student "inmates" became deindividualized and lost time perspective. He has conducted numerous experiments in applied social psychology.

ZUBIN, JOSEPH (1900–1990) Zubin was instrumental in developing techniques of observation and behavior models in psychopathology from physiological, behavioral, genetic, and psychosocial perspectives.

SUBJECT INDEX

A-B-C theory, 794
Abnormality, 1–2
Abreaction, 156
Academic Performance Rating Scale (APRS), 773
Acamprosate, 10, 66
Accommodation, 2–3, 276
Accounts, 488
Achievement:
adolescent development and, 12–13
boredom and, 134
individual differences and, 470, 471
need, 3–4, 281
underachievement and deviance, 281
See also Aptitude testing
Acoustic impedence, 3
Acoustic reflex, 3
Acquired Immunodeficiency Syndrome (AIDS). *See* HIV/AIDS
Action potential, 7–8, 37
Activation rule, 607
Actor-observer asymmetry, 385
Acupuncture, 620
chronic fatigue syndrome and, 178
culture, health, and, 245
Acute Stress Disorder (ASD), 73, 1002, 1003
Adaptation, 8–9, 305
Adderall, 773
Addictions. *See* Substance abuse
Adherence, patient, 670–672
Adjective Check List, 26
Adjustment Disorder, 1002–1003
Adlerian psychotherapy, 252
Adolescent development, 12–13, 578. *See also* Childhood development; Infant development
Adolescent sex offenders. *See* Sexual abuse, adolescent sex offenders
Adoption, 14–18
Adoption Assistance and Child Welfare Act, 17
Adrenal cortex, 18–19
Adrenocorticotropin (ACTH), 708
Adult Attachment Interview, 91
Adventurousness, existential psychology and, 345
Aerial perspective, 276
Affect, 22–24
disorders
CT and, 24
diagnosis, 282
geriatric psychology and, 397
kindling and, 505
dynamic psychology and, 304
learning, behavior modification and, 107
See also Attitudes
Afferent, 24–26
Affiliation need, 26
Aganglionic megacolon, 329
Agape, 84
Age-associated memory impairment (AAMI), 512
Age differences, 26–27
Agency, 440. *See also* Self-efficacy
Aggression:
androgen and, 56
Fragile X and, 380
impulsivity and, 467
logotherapy and, 536
masochism, 561
mob psychology and, 574–575
norepinephrine and, 630
Rosenzweig Picture-Frustration (P-F) study, 837–838
See also Sham rage
Aging:
abuse and neglect, 321–322
anomic aphasia and, 61
behavioral and psychological changes, 530, 700–702
depression and, interpersonal psychotherapy and, 492–493
geriatric neuropsychopathology, 119–120
growth hormone and, 415
IGF-I and, 461
intelligence and, 20, 26–30
differential psychology and, 288
memory and, 512–513
neuropsychology and, 838
pseudodementia and, 738
psychosis and, 513–515
sleep cycles and, 901
social processes and development, 20–22
See also Audition; Discrimination; Geriatric psychology; Gerontology; Geropsychology, clinical; Memory; Residential alternatives; Vision
Agnosias:
apperceptive, 378
neocortex and, 606
Agoraphobia:
anxiety disorders and, 72, 73
Panic Disorder and, 656
psychotherapy and, 315, 316, 776
Agraphia, 30–32, 606
Agricultural psychology, 32–33
Akathisia, 33–35
Al-Anon, 864
Al-Ateen, 864
Alcohol, Drug Abuse, and Mental Health Administration (ADAMHA), 597, 598
Alcoholics Anonymous (AA), 10, 301, 673, 864, 983, 1009
Alcoholism. *See* Substance abuse
Alcohol-Related Neurodevelopmental Disorder (ARND), 369, 371
Alexia, 35–36, 1034
agraphia and, 30, 31
neocortex and, 606
Alienation, political, 36–37. *See also* Vote, disinclination to
Alloparenting, 59
All-or-none law, 37–38
Alpha rhythms, 38–39, 179
Alprazolam:
anxiety disorders and, 74
Huntington's disease and, 620
Altruism, 586–587
Alzheimer's Association, 41
Alzheimer's disease (AD), 29, 39–42, 512, 513, 514, 838
alpha rhythms and, 38
AMPA receptors and, 47, 48
amygdala and, 51
autoreceptors and, 96
CNS disorders and, 159
gerontology and, 399, 400
geropsychology and, 180
IGF-I and, 461, 463
neurochemistry and, 610
neuronal cell death and, 615
olfactory cortex and, 638
Pick's disease and, 706–707
prevention and, 724
priming and, 732
Ambiguity, intolerance of, 832–833
American Academy of Forensic Psychology, 752
American Academy of Sleep Medicine (AASM), 902
American Association for the Advancement of Science, 151

American Psychological Association (APA), 42–44
APPIC and, 74, 75
applied research and, 77
Code of Ethics, 44–45
graduate student organization (APAGS), 43
PsyD and, 295
American Psychological Society (APS), 77
American Psychologist, 43
American Psychology-Law Society, 752
American Sign Language (ASL), 200, 261. *See also* Language, sign
American Society of Clinical Hypnosis, 451
American Speech-Language-Hearing Association (ASHA), 934–935
Americans with Disabilities Act (ADA), 426, 547, 801, 984
Amitriptyline, 68, 273, 1005
Amnesia, 565
Alcohol-Induced Persisting Amnesiic Disorder, 160
CNS disorders and, 159
deception analysis and, 264
declarative memory and, 265
hippocampus and, 432
psychotherapy and, 313
Amok, 245, 249–250
AMPA receptors, 45–48
Amplification, 54–55
Amputation. *See* Phantom limb pain
Amurakh, 249
Amygdala, 49–51
Amyotrophic lateral sclerosis (ALS), 463, 613, 614
Anafranil, 68
Analgesia:
morphine and, 580
opioid receptors and, 643
Analogy, animal model and, 58
Analysis of covariance (ANCOVA), 51–53
Analysis of variance (ANOVA), 51, 52, 53–54
factorial design and, 361
nonparametric statistical tests and, 626
Analytical psychology, 54–55, 252
Androgens, 55–56
Androgynous, 391

Anesthesia, 57–58, 422
Anger management:
  assertiveness training and, 85
  career counseling and, 152
Anhedonia, 256
Anima, 82
Animals:
  ethical treatment of, 336–337
  magnetism, 450
  models, 58–59
  parental behavior, 59–60
  See also Comparative psychology; Ethology
Animus, 82
Anomia. *See* Aphasia, anomic
Anorexia nervosa (AN), 63–64
  adrenal cortex and, 19
  control therapy and, 224
  culture and, 245
  hunger and, 447
  impulsivity and, 467
  marital discord and, 559
  massage therapy and, 992
  tricyclic antidepressants, 1006
Anorgasmia, 432
Anosmia, 637
Antabuse, 65–66. *See also* Substance abuse
Anterograde transport, 364
Anthropology, 66–77
Anthropomorphism, 601
Antiandrogenic medication, 14
Antianxiety drugs, 78–79. *See also specific type*
Antiarrythmics, 49
Antibody-mediated subsystem, 763
Anticonvulsant medications:
  Bipolar Affective Disorder and, 127
  kindling and, 505–506
  phantom limb pain and, 49
  See also specific type
Antidepressant medications, 68–69
  amygdala and, 51
  anxiety disorders, 71–72, 73–74
  autoreceptors and, 95, 96
  Bipolar Affective Disorder and, 125, 127
  brain-derived neurotrophic factor and, 137–138
  Bulimia Nervosa and, 148
  childhood/adolescent depression and, 169, 174
  chronic fatigue syndrome and, 180
  Cyclothymic Disorder and, 257
  Dysthymic Disorder and, 308
  growth hormone and, 416
  nightmares and, 622–623
  phantom limb pain and, 49
  pseudodementia and, 738
  psychosomatic disorders and, 771
  serotonin and, 873
  sleep disorders and, 902
  See also specific type
Antidiuretic hormone (ADH), 708
Antipsychotic medications:
  aging population and, 514
  akathisia and, 34
  Antisocial Personality Disorder and, 70
  autoreceptors and, 96
  hallucinations and, 422
  phantom limb pain and, 49
  tardive dyskinesia and, 973–974
  See also specific type
Antiseizure medications, 380
Antisocial Personality Disorder (APD), 69–70, 166, 167, 763–764
  addiction and, 10
  ADHD and, 11
  Conduct Disorder and, 212
  Cyclothymic Disorder and, 257
  deception analysis and, 264
  impulsivity and, 467
  multisystemic therapy and, 592
Anxiety, 70–72
  amygdala and, 51
  behavior modification and, 108
  biofeedback and, 122
